Preface

The AIEE *Transactions* for 1955 (volume 74) is published in three parts: Part I. Communication and Electronics; Part II. Applications and Industry; and Part III. Power Apparatus and Systems. The papers in each of the three parts are classified according to subject matter as follows:

Part I. Communication and Electronics

- Communication Switching Systems
- Communication Theory
- Radio Communications Systems
- Special Communications Applications
- Telegraph Systems
- Television and Aural Broadcasting Systems
- Wire Communications Systems
- Basic Sciences
- Computing Devices
- Dielectrics
- Electrical Techniques in Medicine and Biology
- Electronics
- Instruments and Measurements
- Magnetic Amplifiers
- Metallic Rectifiers
- Nucleonics
- Solid State Devices

Part II. Applications and Industry

- Air Transportation
- Domestic and Commercial Applications
- Land Transportation
- Marine Transportation
- Production and Application of Light
- Chemical Industry
- Electric Heating
- Electric Welding
- Feedback Control Systems
- General Industry Applications
- Industrial Control
- Industrial Power Rectifiers
- Industrial Power Systems
- Mining and Metal Industry
- Petroleum Industry

Part III. Power Apparatus and Systems

- Carrier Current
- Insulated Conductors
- Power Generation
- Protective Devices
- Relays
- Rotating Machinery
- Substations
- Switchgear
- System Engineering
- Transformers
- Transmission and Distribution

- Education
- Safety
- Research

Each part has been indexed separately in the back of that particular part. The three parts are not cross-referenced; hence the user should determine first whether the subject matter of the paper desired is in the field of communication and electronics, applications and industry, or power apparatus and systems. Papers are listed in the subject index under several key words in the titles. The original numbers assigned to the papers are given in the author index. Volume 74 contains the technical papers and related discussions presented at these meetings:

1. Winter General Meeting, New York, N. Y., January 31–February 4, 1955.
2. Southern District Meeting, St. Petersburg, Fla., April 13–15, 1955.
3. Middle Eastern District Meeting, Columbus Ohio, May 4–6, 1955.
4. Summer General Meeting, Swampscott, Mass., June 27–July 1, 1955.
5. Pacific General Meeting, Butte, Mont., August 15–17, 1955.
6. Fall General Meeting, Chicago, Ill., October 3–7, 1955.

Statements and opinions given in the papers and discussions published in *Transactions* are the expressions of the contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Power Apparatus and Systems Index for 1955

1. Technical Subject Index

A-C Generators for Improved Performance, Rewinding. Seline........472–4; disc. 474
A-C Motor Windings, Measurement of Resistance of Energized. Waldschmidt.....1303–04; disc. 1305
A-C Network Analyzers, Combination Load-Flow and Stability Equivalent for Power System Representation on. Brown, Cloues..........782–6; disc. 786
A-C Resistance of Conventional Strand Power Cables in Nonmetallic Duct and in Iron Conduit. Burrell, Morris........1014–21; disc. 1021
A-C Test Circuits, Testing of D-C Interrupters on. Chen, Boehne........1073–9; disc. 1079
ACSR Conductor Sizes for Distribution Systems, A Method for Determining Economical. Funkhouser, Huber........479–83; disc. 483
ACSR, Measurement of Resistance and Reactance of Expanded. Tompkins, Jones, Tuttle........368–73; disc. 373
Air-Break Disconnect Switch, Power Auto-transformer Current Interruption with an. Anderson........1157–63
Air Circuit Breaker, A New High-Capacity Anode. Bottonari, Sprow..........1297–1302; disc. 1302
Air Circuit Breaker for 5,000,000 Kva, A 69-Kv Compressed. Kane, Walker........705–09; disc. 709
Air Circuit Breaker Interrupters, Flux Measurements in Magnetic. Carter..........1062–5; disc. 1065
Air-Disconnect Switches, High-Current Testing of. Gostin........21–5
Air Gap—A Novel Asynchronous Frequency Changer, Double-Energy Conversion in an. LaPierre, Louis........1373–5; disc. 1376
Air Magnetic Circuit Breaker of Simplified Design, A New 500-Megavolt-Ampere. Reilly, Weston........1093–8; disc. 1098
Alignment of Vertical-Shaft Hydroelectric Units as Practiced by Tennessee Valley Authority, Mechanical. Norris........586–9, disc. 589
Alternators, Design Principles of Flux-Switch. Rauch, Johnson........1261–8; disc. 1268
Aluminum Bus for Substations, Development of a Welded. Asbury, Hartman.......834–8; disc. 838
Aluminum Conductor on Transmission Lines, The Use of All-. Wright, Lambert.......849–53; disc. 853
Aluminum Connectors, Nontension. Boyer, Korges........844–7; disc. 847
Aluminum Distribution Conductors in the Philadelphia Electric Company, Design Problems and Operating Experience with. Nelson, Garrett........825–8; disc. 828...
Aluminum Distribution Systems, Eight Years' Experience With All-. Carpenter, Thornton........828–32; disc. 832
Aluminum in Heavy Current Conductors. Deans........1192–8; disc. 1198
Aluminum in Windings for Dry-Type Power Transformers, Experiences With the Use of. Tipton........1201–04
Aluminum-Sheathed Control Cable. McIlveen........1377–84; disc. 1384
Aluminum-Sheathed Power Cable. Del Mar, Merrell........292–8; disc. 298
Aluminum Squirrel Cage Rotors for Induction Motors, The Transient Stalled Temperature Rise of Cast. Rosenberry........819–24; disc. 824
Aluminum Widely Used in Power Switchgear. Talento........839–43; disc. 843
Amplifier, A Circuit Approach to the Analysis of a 2-Stage Dynamoelectric. Burtness........440–9; disc. 449
Analogue Solution of Cable Heat Flow Problems, An. deHaas, Sandiford, Cameron.....315–18; disc. 318
Analysis of a 2-Stage Dynamoelectric Amplifier, A Circuit Approach to the. Burtness........440–9; disc. 449
Analysis of Fault Currents for High-Voltage Circuit-Breaker Interruption. Lantz........41–5
Analyzers, Combination Load-Flow and Stability Equivalent for Power System Representation on A-C Network. Brown, Cloues....782–6; disc. 786
Analyzing Electric Machines, Two-Axis Method. Tang, Cosgriff........1449–55
Anechoic Chamber for Noise Tests on Large Power Transformers, An. Benoit, Hemmes, Schulz..50–6
Anode Air Circuit Breaker, A New High-Capacity. Bottonari, Sprow..........1297–1302; disc. 1302
Apparatus Noise Measurement. Wells........1170–3
Application of a New Nontracking Butyl to High-Voltage Instrument Transformers, The. Pfuntner, Norman, Wilterdink........1173–6
Application of Business Machines to Electrical Utility Load Forecasting, The. Gruetter........854–8
Application of Statistics to Motor Testing. Oldenkamp........815–18; disc. 818
Application of Volume Theory of Dielectric Strength to Oil Circuit Breakers. Wilson, Streater, Tuohy........677–84; disc. 684.
Approach to the Calculation of Synchronous Machine Reactances, A New. Talaat. Part I........176–82; disc. 182
Approach to the Definition of Excitation System Response, An. Bliss..........1008–12; disc. 1012
Arc Erosion of Electric Contact Materials, High-Current. Wilson........657–64; disc. 664
Arc Furnace Loads, Voltage Dip and Synchronous Condenser Swings Caused by. Concordia...951–6
Arc Furnaces—Electrical Characteristics and Corrective Equipment, Two Large Electric. Luther, Ghesquiere, Quick........1401–05; disc. 1406
Area Supply Methods, General Study of. Casazza, Rankin........1328–34; disc. 1334–5
Armature End Iron of Large Turbine Generators, Stray Losses in the. Winchester........381–9; disc. 389
Armature Windings, Some Factors Influencing the Temperature Rise of. Liwschitz-Garik......752–9
Armatures, Correlation of Temperature Measurements on D-C. Gerbetz, Ewing........391–4; disc. 395
Asynchronous Frequency Changer, Double-Energy Conversion in an Air Gap—A Novel. LaPierre, Louis........1373–5; disc. 1376
Attenuation in Power Cables, Surge. Valentine, Dillard, Clayton........1115–21; disc. 1122
Audible Noise Control, Recent Contributions to Transformer. Conover, Ringlee........77–90; disc. 90
Automatic Load Frequency Control System for Central Station Power. Ehrenberg........787–95
Automatic Load Shedding. (Committee Report)........1143–5; disc. 1145
Automatically Switched Capacitors in Steps on a Single Distribution Feeder. Fowler, Thomas........311–14; disc. 314
Autotransformer Current Interruption with an Air-Break Disconnect Switch, Power. Anderson........1157–63
Autotransformers, Thyrite Protection for Series Windings of. Albright........150–4; disc. 154
Auxiliary Busses, Transfer of Steam-Electric Generating-Station. Lewis, Marsh........322–30; disc. 330
Auxiliary Busses, Transfer Tests on Station. Backer, Barth, Huse, Taylor........1441–5; disc. 1446
Auxiliary Drive Motors in Power Plants, Economic Selection of. Gross, Bobrowicz........1237–46; disc. 1246
Axis Method of Analyzing Electric Machines, Two-. Tang, Cosgriff........1449–55

B

Balancing Double-Wye High-Voltage Capacitor Banks. Compton........573–8; disc. 578
Bank Relaying Systems, Line and Transformer. Blackburn, Rockefeller........334–9; disc. 339
Banks, Balancing Double-Wye High-Voltage Capacitor. Compton........573–8; disc. 578
Banks, Intermittently Increased Kilovar Output of Large Capacitor. Minder.......749–51; disc. 751
Bars of Squirrel-Cage Rotors, Computation of Skin Effect in. Liwschitz-Garik.....768–70; disc. 771
Basic Functions in Network Distribution Systems, The Limiter—Its. Xenis........913–15; disc. 944, 1463
Basic Sequence Networks. Kirschbaum........771–4
Behavior of High Voltage Busses and Insulators During Short Circuits. Milton, Chambers........742–6; disc. 746
Bibliography and Summary of Fault Location Methods. (Committee Report)........1423–7; disc. 1427
Bibliography of Relay Literature—1950–52. Gross........45–8
Blondel Theory, Current Loci of Salient-Pole Synchronous Motors: An Extension of. Douglas........1080–2; disc. 1082
Breakdown of Fully Impregnated Paper Insulation for High-Voltage Cables, Research on the Electric. Gazzana Priaroggia, Palandri..1343–57; disc. 1357
Bureau of Reclamation 230-Kv Transmission Lines in North Dakota. Austin........1147–51
Bus for Substations, Development of a Welded Aluminum. Asbury, Hartman........834–8; disc. 838
Business Machines to Electrical Utility Load Forecasting, The Application of. Gruetter........854–8
Busses and Insulators During Short Circuits, Behavior of High Voltage. Milton, Chambers........742–6; disc. 746
Busses, Transfer of Steam-Electric Generating-Station Auxiliary. Lewis, Marsh........322–30; disc. 330
Busses, Transfer Tests on Station Auxiliary. Backer, Barth, Huse, Taylor........1441–5; disc. 1446
Butyl-Rubber-Insulated Power Cable, Design and Evaluation of. Carroll, Lee, McKinley........1204–12; disc. 1212
Butyl to High-Voltage Instrument Transformers, The Application of a New Nontracking. Pfuntner, Norman, Wilterdink........1173–6

C

Cable, Aluminum-Sheathed Control. McIlveen........1377–84; disc. 1384
Cable, Aluminum-Sheathed Power. Del Mar, Merrell........292–8; disc. 298
Cable at High Frequency, Characteristics of Single-Conductor Electric. Sabol.....1280–5; disc. 1285
Cable by Oven Heating Tests, High Temperature Classification of Rubber and Rubberlike Insulation of Network. Couch, Crowdes........930–4; disc. 944, 1463
Cable Characteristics, The Co-ordination of Power and Communication. Short........281–7; disc. 287
Cable, Design and Evaluation of Butyl-Rubber-Insulated Power. Carroll, Lee, McKinley........1204–12; disc. 1212
Cable Heat Flow Problems, An Analogue Solution of. deHaas, Sandiford, Cameron.....315–18; disc. 318
Cable in Duct, Time-Current Damage Characteristics. Porter........919–21; disc. 944, 1463
Cable Systems, Oil Flow and Pressure Calculations for Pipe Type. (Committee Report)........251–9; disc. 259
Cable Temperature Transients, An Improved Approximate Technique for Calculating. Van Wormer........277–80; disc. 280
Cables, A Mathematical Method for Determining Insulation Damage Curves for Network. Kolks........934–8; disc. 944, 1463
Cables, A Method of Measurement of Carrier Characteristics of Power. Sparlin, Moynihan........31–3
Cables, Characteristic Properties of Secondary Network. Rosch........939–44; disc. 944, 1463
Cables, Freezing Oil-Type Pipe. Merrell........1023–31; disc. 1031
Cables in Nonmetallic Duct and in Iron Conduit, A-C Resistance of Conventional Strand Power. Burrell, Morris........1014–21; disc. 1021
Cables in Ontario, Gas-Pressurized 120-Kv and 161-Kv Pipe Type. Kozak, Prescott.....184–92; disc. 192
Cables, Mineral-Insulated Metallic-Sheathed. Jordan, Eager........198–212; disc. 212

Cables, Overload Classifications for Secondary Network. Graham..........916–19; disc. 944, 1463
Cables, Research on the Electric Breakdown of Fully Impregnated Paper Insulation for High-Voltage. Gazzana Priaroggia, Palandri..1343–57; disc. 1357
Cables, Some Performance Characteristics of High-Voltage Rubber-Insulated. Rosch..........1219–24; disc. 1224
Cables, Surge Attenuation in Power. Valentine, Dillard, Clayton..........1115–21; disc. 1122
Cage Winding Protective Relay for Synchronous Machines, Improved Fast-Acting Thermal Relay and Its Application as a. Baude.....349–53; disc. 353
Calculating Cable Temperature Transients, An Improved Approximate Technique for. Van Wormer..........277–80; disc. 280
Calculating Voltage Regulation Using Unit Impedance Power Reactive Diagrams, A Simplified Method of. Butler..........304–10; disc. 310
Calculation of Network Impedances, Digital. Glimn, Habermann, Henderson, Kirchmayer..........1285–95; disc. 1295
Calculation of Synchronous Machine Reactances, A New Approach to the. Talaat:
  Part I..........176–82; disc. 182
Calculation of the Complete Time/Current Characteristics of Cartridge Fuses With Single Wire Element, The. Guile........1108–15; disc. 1115
Calculations and Test Results, D-C Machines—Short-Circuit. O'Connor, Cybulski....222–30; disc. 230
Calculations, D-C Machines—Method for Short-Circuit. Cybulski, O'Connor..........214–21
Calculations for Pipe-Type Cable Systems, Oil Flow and Pressure. (Committee Report)...251–9; disc. 259
Calculations in Power System Transient Stability Studies, A Rational Method for the Step-by-Step. Norinder..........1087–91; disc. 1091
Calculations to Transmission Line Design, Practical Application of Sag and Tension. Lummis, Fischer..........402–13; disc. 413
Capacitance Switching Devices, Test Circuits for. Darrow, Phillips, Schultz, Shores.....624–34; disc. 634
Capacitance-Switching Facilities at the Switchgear Development Laboratory. Williams, Mankoff, Schneider..........375–80; disc. 380
Capacitance Switching, Some Fundamentals on. Johnson, Schultz, Schultz, Shores..........727–36; disc. 736
Capacitors in Steps on a Single Distribution Feeder Automatically Switched. Fowler, Thomas..........311–14; disc. 314
Capacitor Banks, Balancing Double-Wye High-Voltage. Compton..........573–8; disc. 578
Capacitor Banks, Intermittently Increased Kilovar Output of Large. Minder.......749–51; disc. 751
Capacitors, Report on the Operation of Switched. (Committee Report)..........1255–60; disc. 1260
Capture Effect in a Narrow-Band Frequency Modulated System, An Investigation of the. Hedges..........289–91; disc. 292
Carrier Characteristics on Power Cables, A Method of Measurement of. Sparlin, Moynihan........31–3
Carrier Coupling—An Analysis, Power-Line. Bienhoff..........1163–70
(Carrier Current) An Investigation of the Capture Effect in a Narrow-Band Frequency Modulated System. Hedges..........289–91; disc. 292
(Carrier Current) Design of the Adjustable Lin-O-Phase Filter. Lee..........273–7; disc. 277
(Carrier Current) Microwave System Parameters for Reliable Communications. Alvira, Corbell..........1100–07; disc. 1107
(Carrier Current) Quadriphase—A New Approach to Time Division Multiplexing. Evans, Lowe..........900–03
(Carrier Current) Recommendations for Improving Reliability of Stand-by Engine Generators for Microwave Communications Systems. Tharp..........261–6; disc. 266
Carrier-Frequency Noise on Power Lines, A Study of. Moynihan, Sparlin:
  Part IV. Conclusion of Field Measurements..........795–800
Carrier Pilot Relaying, Future Application Needs of. Cramer, Kringa..........1233–5; disc. 1235
Cartridge Fuses With Single Wire Element, The Calculation of the Complete Time/Current Characteristics of. Guile..........1108–15; disc. 1115
Casting of Dry-Type Current Transformers, Epoxy Resin. Farneth, Gallousis.......194–7; disc. 197
Central Station Power, Automatic Load Frequency Control System for. Ehrenberg..........787–95
Chamber for Noise Tests on Large Power Transformers, An Anechoic. Benoit, Hemmes, Schulz......50–6
Changer, Double-Energy Conversion in an Air Gap—A Novel Asynchronous Frequency. LaPierre, Louis..........1373–5; disc. 1376
Characteristic Properties of Secondary Network Cables. Rosch..........939–44; disc. 944, 1463
Characteristics and Application, Limiters, Their Design. Heller, Matthysse..........924–30; disc. 944
Characteristics and Corrective Equipment, Two Large Electric Arc Furnaces—Electrical. Luther, Ghesquiere, Quick..........1401–05; disc. 1406
Characteristics of Cartridge Fuses With Single Wire Element, The Calculation of the Complete Time/Current. Guile..........1108–15; disc. 1115
Characteristics of High-Voltage Rubber-Insulated Cables, Some Performance. Rosch..........1219–24; disc. 1224
Characteristics of Single-Conductor Electric Cable at High Frequency. Sabol.......1280–5; disc. 1285
Characteristics of Wood and Suspension Insulators in Series, Insulation. Clayton, Shankle..........1305–11; disc. 1312
Characteristics on Power Cables, A Method of Measurement of Carrier. Sparlin, Moynihan.......31–3
Characteristics, The Co-ordination of Power and Communication Cable. Short........281–7; disc. 287
Circuit Approach to the Analysis of a 2-Stage Dynamoelectric Amplifier, A. Burtness..........440–9; disc. 449
Circuit Breaker, A New High-Capacity Anode Air. Bottonari, Sprow..........1297–1302; disc. 1302
Circuit Breaker at Philip Sporn Power Plant, Field Tests on a 138-Kv High-Speed Oil. Naef, Hambrick..........710–24; disc. 724
Circuit Breaker for 5,000,000 Kva, A 69-Kv Compressed Air. Kane, Walker......705–09; disc. 709
Circuit Breaker Interrupters, Flux Measurements in Magnetic Air. Carter..........1062–5; disc. 1065
Circuit-Breaker Interruption, Analysis of Fault Currents for High-Voltage. Lantz..........41–5
Circuit Breaker of Simplified Design, A New 500-Megavolt-Ampere Air Magnetic. Reilly, Weston..........1093–8; disc. 1098
Circuit Breaker Recovery Voltages Associated with 2-Phase-to-Ground Short Circuits, Short-Circuit Currents and. Skeats..........688–93; disc. 693
Circuit Breakers, Application of Volume Theory of Dielectric Strength to Oil. Wilson, Streater, Tuohy..........677–84; disc. 684
Circuit Breakers, Dynamics of High-Capacity Outdoor Oil. Barkan..........671–6; disc. 676
Circuit Breakers for Switching Long 230-Kv Lines, Design Problems and Field Tests Concerning. Umphrey, Marsden..........693–701; disc. 701
Circuit Breakers, The Results of 7 Years' Experience with High-Capacity Outdoor Oil. Balentine, Darrow..........665–70; disc. 671
Circuit for the Concatenation of Induction Motors, Equivalent. Ku..........1214–18; disc. 1219
Circuit Transient Recovery Voltage Characteristics of Electric Power Systems, A Method for Studying. Kotheimer..........1083–6; disc. 1086
Circuit, Weighted Mutual Reactances for a Triple-Cage Motor. Martin..........765–8
Circuitry for Remotely Operated Electric Utility Substations, Control. Derr, Metz....450–9; disc. 459
Circuits, A Power Class Recloser for Higher Speed Clearing of Distribution. Field, Leatherberry..........986–91; disc. 991
Circuits for Capacitance Switching Devices, Test. Darrow, Phillips, Schultz, Shores..........624–34; disc. 634
Circuits for Single-Phase Motors, Equivalent. Siemon..........1335–42; disc. 1342
Circuits, Testing of D-C Interrupters on A-C Test. Chen, Boehne..........1073–9; disc. 1079
Clearing of Distribution Circuits, A Power Class Recloser for Higher Speed. Field, Leatherberry..........986–91; disc. 991
Coincident-Outage Probability in Secondary Network Vaults. Reps..........580–5; disc. 585
Combination Load-Flow and Stability Equivalent for Power System Representation on A-C Network Analyzers. Brown, Cloues.......782–6; disc. 786
Commercial Areas, Economics of Higher Primary and Secondary Voltages for. Lawrence, Reps..........1034–45; disc. 1945
(Committee Report) Automatic Load Shedding. (55-615)..........1143–5; disc. 1145
(Committee Report) Bibliography and Summary of Fault Location Methods. (55-709)..........1423–7; disc. 1427
(Committee Report) Effect of Shock and Vibration on Relays. (55-97)..........398–400; disc. 400
(Committee Report) Oil Flow and Pressure Calculations for Pipe-Type Cable Systems. (55-32)..........251–9; disc. 259
(Committee Report) Proposed Test Code for Functional Temperature Endurance Tests of Ventilated Dry Type Power and Distribution Transformers. (55-435)..........971–5; disc. 975
(Committee Report) Report on the Operation of Switched Capacitors. (55-710)..........1255–60; disc. 1260
(Committee Report) Review of the Factors Concerned with the Use of Protective Devices Shunting Reactors. (55-557)..........903–13
(Committee Report) Supervisory Control and Associated Telemetering Equipment—A Survey of Current Practice. (55-128)..........36–8
(Committee Report) System Planning Practices. (55-529)..........896–900
Communication Cable Characteristics, The Co-ordination of Power and. Short........281–7; disc. 287
Communications Equipment, Protection of Personnel Against Electrical Shock Hazards in Central Office. Jones..........893–6
Communications, Microwave System Parameters for Reliable. Alvira, Corbell.....1100–07; disc. 1107
Communications Systems, Recommendations for Improving Reliability of Stand-by Engine Generators for Microwave. Tharp....261–6; disc. 266
Compounds in Transformer Oil, Interpretation and Significance of Tests Indicating the Concentration of Polar. Johnson..........774–80; disc. 780
Compressed Air Circuit Breaker for 5,000,000 Kva, A 69-Kv. Kane, Walker.......705–09; disc. 709
Computation of Skin Effect in Bars of Squirrel-Cage Rotors. Liwschitz-Garik.......768–70; disc. 771
Computer, An Incremental Cost of Power-Delivered. Early, Phillips, Shreve..........529–34; disc. 534
Computer for Economic Scheduling and Control of Power Systems, A. Morrill, Blake..........1136–41; disc. 1141
Concatenation of Induction Motors, Equivalent Circuit for the. Ku..........1214–18; disc. 1219
Concentration of Polar Compounds in Transformer Oil, Interpretation and Significance of Tests Indicating the. Johnson..........774–80; disc. 780
Condenser Swings Caused by Arc Furnace Loads, Voltage Dip and Synchronous. Concordia..........951–6
Conductor Materials for Turbine Generators, Improved Field. Holley, Savidge..........72–6
Conductor on Transmission Lines, The Use of All Aluminum. Wright, Lambert...849–53; disc. 853
Conductor Sizes for Distribution Systems, A Method for Determining Economical ACSR. Funkhouser, Huber..........479–83; disc. 483
Conductors, Aluminum in Heavy Current. Deans..........1192–8; disc. 1198
Conductors in the Philadelphia Electric Company, Design Problems and Operating Experience with Aluminum Distribution. Nelson, Garrett..........825–8; disc. 828
Conduit, A-C Resistance of Conventional Strand Power Cables in Nonmetallic Duct and in Iron. Burrell, Morris..........1014–21; disc. 1021
Connectors, Nontension Aluminum. Boyer, Korges..........844–7; disc. 847
Constants for the General Transmission Loss Equation, A New Method of Determining. Early, Watson..........1417–21; disc. 1421
Constants With Tensors, ORACLE Computes Line. Shipley, Hochdorf, Watson......1052–6; disc. 1056
Contact Life of Voltage-Regulating Relays. Schoendube, Elliott..........1398–1400; disc. 1401
Contact Materials, High-Current Arc Erosion of Electric. Wilson..........657–64; disc. 664
Control and Associated Telemetering Equipment—A Survey of Current Practice, Supervisory. (Committee Report)..........36–8
Control Cable, Aluminum-Sheathed. McIlveen..........1377–84; disc. 1384
Control Circuitry for Remotely Operated Electric Utility Substations. Derr, Metz..........450–9; disc. 459
Control of Electrostatic Voltage Distribution in Power Transformer Design. Bennon, Cossaart..........1122–5; disc. 1125
Control System for Central Station Power, Automatic Load Frequency. Ehrenberg..........787–95
Controls for Step Voltage Regulators. Lennox..........1407–09; disc. 1410
Conventional Strand Power Cables in Nonmetallic Duct and in Iron Conduit, A-C Resistance of. Burrell, Morris..........1014–21; disc. 1021
Conversion in an Air Gap—A Novel Asynchronous Frequency Changer, Double-Energy. LaPierre, Louis..........1373–5; disc. 1376
Co-ordination of Hydro and Steam Generation. Watchorn..........142–8; disc. 148
Co-ordination of Power and Communication Cable Characteristics, The. Short.......281–7; disc. 287
Co-ordination of Secondary Network Protection. Leinbach, Brookes..........922–4; disc. 944, 1463
Cores During Impulse Testing, Magnetization of Transformer. Beavers, Holcomb, Leoni..........118–23; disc. 123
Corona on Traveling Waves, Effects of. Wagner, Lloyd..........858–72
Corona Studies—In Relation to Insulation. Liao, Nye, Brustle, Anderson.......1046–50; disc. 1050
Corrective Equipment, Two Large Electric Arc Furnaces—Electrical Characteristics. Luther, Ghesquiere, Quick..........1401–05; disc. 1406
Correlation of Temperature Measurements on D-C Armatures. Gerbetz, Ewing......391–4; disc. 395
Cost of Power-Delivered Computer, An Incremental. Early, Phillips, Shreve..........529–34; disc. 534

Coupled Windings, Oscillations of. Abetti, Adams, Maginnis..........12–21
Coupling—An Analysis, Power-Line Carrier. Bischoff..........1163–70
Current Conductors, Aluminum in Heavy. Deans..........1192–8; disc. 1198
Current Interruption with an Air-Break Disconnect Switch, Power Autotransformer. Anderson..........1157–63
Current-Limiting Fuses, Ribbon Elements for High-Voltage. Powell, Schuck..........635–41; disc. 641
Current Loci of Salient-Pole Synchronous Motors: An Extension of Blondel Theory. Douglas..........1080–2; disc. 1082
Current Ratings for Step Regulators, Increased. Sealey..........737–42; disc. 742
Current Sources for Electric Defibrillation, Field. Betz..........33–6
Current Transformers, Epoxy Resin Casting of Dry-Type. Farneth, Gallousis..........194–7; disc. 197
Currents and Circuit-Breaker Recovery Voltages Associated with 2-Phase-to-Ground Short Circuits, Short-Circuit. Skeats..........688–93; disc. 693
Currents for High-Voltage Circuit-Breaker Interruption, Analysis of Fault. Lantz..........41–5
Currents in Turbine Generators, Eccentricity, Vibration and Shaft. Rosenberg..........38–41
Curves for Network Cables, A Mathematical Method for Determining Insulation Damage. Kolks..........934–8; disc. 944
Curves for Small Motors from Motor Tests, Developing Iron Loss. Shaneman..........1176–9

D-C Armatures, Correlation of Temperature Measurements on. Gerbetz, Ewing..........391–4; disc. 395
D-C Interrupters on A-C Test Circuits, Testing of. Chen, Boehne..........1073–9; disc. 1079
D-C Machines—Method for Short-Circuit Calculations. Cybulski, O'Connor..........214–21
D–C Machines: Response to Impact Excitation. Brockman, Linkous..........500–03; disc. 503
D-C Machines—Short Circuit Calculations and Test Results. O'Connor, Cybulski...222–30; disc. 230
Damage Characteristics, Cable in Duct, Time-Current. Porter..........919–21; disc. 944, 1463
Damage Curves for Network Cables, A Mathematical Method for Determining Insulation. Kolks..........934–8; disc. 944, 1463
Defibrillation, Electric. Kouwenhoven, Milnor..........561–4; disc. 564
Defibrillation, Field Current Sources for Electric. Betz..........33–6
Definition of Excitation System Response, An Approach to the. Bliss..........1008–12; disc. 1012
Design and Evaluation of Butyl-Rubber-Insulated Power Cable. Carroll, Lee, McKinley..........1204–12; disc. 1212
Design and Operation of Secondary Network Systems, The Use of Probability in the. Neagle, Nelson..........567–72; disc. 572
Design Characteristics and Application, Limiters, Their. Heller, Matthysse..........924–30; disc. 944, 1463
Design, Investigation of European Practices in Power Line. Fritz..........505–09; disc. 509
Design of Induction Torque Motors and Servomotors, Optimum. Weiss..........809–15
Design of Large Induction Motors, Sonance. Wall..........1189–92
Design of the Adjustable Lin-O-Phase Filter. Lee..........273–7; disc. 277
Design Principles of Flux-Switch Alternators. Rauch, Johnson..........1261–8; disc. 1268
Design Problems and Field Tests Concerning Circuit Breakers for Switching Long 230-Kv Lines. Umphrey, Marsden..........693–701; disc. 701
Design Problems and Operating Experience With Aluminum Distribution Conductors in the Philadelphia Electric Company. Nelson, Garrett..........825–8; disc. 828
Detection of Grounds in Generator Field Windings. Barkle, Sterrett, Fountain..........467–70; disc. 470
Detector for Synchronous Generators, A Transductor Type Field Ripple. McConnell..........476–9; disc. 479
Determination of Incremental and Total Loss Formulas from Functions of Voltage Phase Angles, The. Cahn..........161–71; disc. 171
Determining Constants for the General Transmission Loss Equation, A New Method of. Early, Watson..........1417–21; disc. 1421
Developing Iron Loss Curves for Small Motors from Motor Tests. Shaneman..........1176–9
Development of a Welded Aluminum Bus for Substations. Asbury, Hartman..........834–8; disc. 838
Development of Small Hydroelectric Sites in Western North Carolina. Gnuse..........65–8
Devices, Test Circuits for Capacitance Switching. Darrow, Phillips, Schultz, Shores..........624–34; disc. 634
Diagrams, A Simplified Method of Calculating Voltage Regulation Using Unit Impedance Power Reactive. Butler..........304–10; disc. 310
Dielectric Strength to Oil Circuit Breakers, Application of Volume Theory of. Wilson, Streater, Tuohy..........677–84; disc. 684
Digital Calculation of Network Impedances. Glimn, Habermann, Henderson, Kirchmayer..........1285–95; disc. 1295
Direct-Stroke Protection of High-Voltage Switching Stations and Transformers. Griscom, Dillard, Hileman..........354–65; disc. 365
Disconnecting Switches, Results of High-Current Tests on 161-Kv. McNerney..........104–08; disc. 108
Dissymmetry Harmonics, Single-Phase Induction Motor Noise Due to. Muster, Wolfert..........1365–72; disc. 1372
Distribution Circuits, A Power Class Recloser for Higher Speed Clearing of. Field, Leatherberry..........986–91; disc. 991,
Distribution Conductors in the Philadelphia Electric Company, Design Problems and Operating Experience with Aluminum. Nelson, Garrett..........825–8; disc. 828
Distribution Feeder, Automatically Switched Capacitors in Steps on a Single. Fowler, Thomas..........311–14; disc. 314
Distribution in Power Transformer Design, Control of Electrostatic Voltage. Bennon, Cossaart..........1122–5; disc. 1125
(Distribution) Measurement of Resistance and Reactance of Expanded ACSR. Tompkins, Jones, Tuttle..........368–73; disc. 373
Distribution-Substation and Primary Feeder Planning. Denton, Reps..........484–97; disc. 497
Distribution System Parameters, Power. Kidder, Neher..........125–40; disc. 140
Distribution Systems, A Method for Determining Economical ACSR Conductor Sizes for. Funkhouser, Huber..........479–83; disc. 483
Distribution Systems, Eight Years' Experience with All-Aluminum. Carpenter, Thornton..........828–32; disc. 832
Distribution Systems, The Limiter—Its Basic Functions in Network. Xenis..........913–15; disc. 944, 1463
Distribution Transformers, Functional Life Expectancy Tests for Liquid Filled. Lockie..........977–82; disc. 982
Distribution Transformers, Impulse Tests on Low-Voltage Windings of. Holcomb..........1152–5; disc. 1155
Division Multiplexing, Quadriphase—A New Approach to Time. Evans, Lowe..........900–03
Double-Energy Conversion in an Air Gap—A Novel Asynchronous Frequency Changer. LaPierre, Louis..........1373–5; disc. 1376
Double-Wye High-Voltage Capacitor Banks, Balancing. Compton..........573–8; disc. 578
Dry-Type Current Transformers, Epoxy Resin Casting of. Farneth, Gallousis..........194–7; disc. 197
Dry-Type Power and Distribution Transformers, Proposed Test Code for Functional Temperature Endurance Tests of Ventilated. (Committee Report)..........971–5; disc. 975.
Dry-Type Power Transformers, Experiences With the Use of Aluminum in Windings for. Tipton..........1201–04
Dry-Type Power Transformers, Functional Life Evaluation of Group-2. Zambell..........956–70
Dry-Type Transformer Insulation, Evaluation and Application of Silicone-Organic Resin Combinations for. Simmons, Scheideler..........155–60; disc. 160
Dry-Type Transformers, Functional Life Tests of Insulation Systems for. Narbut..........1057–61; disc. 1061
Dry-Type Transformers, Functional Temperature Endurance Tests on a Silicone Glass Fiber Insulation System for. Manning..........91–8; disc. 98
Duct and in Iron Conduit, A-C Resistance of Conventional Strand Power Cables in Nonmetallic. Burrell, Morris..........1014–21; disc. 1021
Duct, Time-Current Damage Characteristics, Cable in. Porter..........919–21; disc. 944, 1463
Durability Testing of Valve Type Lightning Arresters, Transient. Kalb, Yost..........521–6; disc. 526
Dynamics of High-Capacity Outdoor Oil Circuit Breakers. Barkan..........671–6; disc. 676
Dynamoelectric Amplifier, A Circuit Approach to the Analysis of a 2-Stage. Burtness..........440–9; disc. 449

(Insulated Conductors) The Co-ordination of Power and Communication Cable Characteristics. Short....281–7; disc. 287
(Insulated Conductors) The Limiter—Its Basic Functions in Network Distribution Systems. Xenis....913–15; disc. 944, 1463
(Insulated Conductors) Time Current Damage Characteristics, Cable in Duct. Porter....919–21; disc. 944, 1463
Insulated Metallic-Sheathed Cables, Mineral. Jordan, Eager....198–212; disc. 212
Insulated Power Cable, Design and Evaluation of Butyl-Rubber-. Carroll, Lee, McKinley....1204–12; disc. 1212
Insulation Characteristics of Wood and Suspension Insulators in Series. Clayton, Shankle....1305–11; disc. 1312
Insulation, Corona Studies—In Relation to. Liao, Nye, Brustle, Anderson....1046–50; disc. 1050
Insulation Damage Curves for Network Cables, A Mathematical Method for Determining. Kolks....934–8; disc. 944, 1463
Insulation, Evaluation and Application of Silicone-Organic Resin Combinations for Dry-Type Transformer. Simmons, Scheideler....155–60; disc. 160
Insulation for High-Voltage Cables, Research on the Electric Breakdown of Fully Impregnated Paper. Gazzana Priaroggia, Palandri....1343–57; disc. 1357
Insulation, Modern High-Voltage Rubber. Couch, Hunt, Kenney, Ware....1387–97; disc. 1398
Insulation of Network Cable by Oven-Heating Tests, High-Temperature Classification of Rubber and Rubberlike. Couch, Crowdes....930–4; disc. 944, 1463
Insulation System for Dry-Type Transformers, Functional Temperature Endurance Tests on a Silicone Glass Fiber. Manning....91–8; disc. 98
Insulation Systems for Dry-Type Transformers, Functional Life Tests of. Narbut....1057–61; disc. 1061
Insulators During Short Circuits, Behavior of High-Voltage Busses and. Milton, Chambers....742–6; disc. 746
Insulators in Series, Insulation Characteristics of Wood and Suspension. Clayton, Shankle....1305–11; disc. 1312
Interconnected Power Systems, Load-Phase Tie-Line Energy Control of. Cahen....1–5
Intermittently Increased Kilovar Output of Large Capacitor Banks. Minder....749–51; disc. 751
Interpretation and Significance of Tests Indicating the Concentration of Polar Compounds in Transformer Oil. Johnson....774–80; disc. 780
Interrupters, Flux Measurements in Magnetic Air Circuit Breaker. Carter....1062–5; disc. 1065
Interrupters on A-C Test Circuits, Testing of D-C. Chen, Boehne....1073–9; disc. 1079
Interruption, Analysis of Fault Currents for High-Voltage Circuit-Breaker. Lantz....41–5
Interruption with an Air-Break Disconnect Switch, Power Autotransformer Current. Anderson....1157–63
Investigation of European Practices in Power Line Design. Fritz....505–09; disc. 509
Investigation of the Capture Effect in a Narrow-Band Frequency-Modulated System, An. Hedges....289–91; disc. 292
Investigation of the Economic Size of Steam-Electric Generating Units, An. Kirchmayer, Mellor O'Mara, Stevenson....600–09; disc. 609
Iron Conduit, A-C Resistance of Conventional Strand Power Cables in Nonmetallic Duct and in. Burrell, Morris....1014–21; disc. 1021
Iron Loss Curves for Small Motors from Motor Tests, Developing. Shaneman....1176–9
Iron of Large Turbine Generators, Stray Losses in the Armature End. Winchester....381–9; disc. 389
Iron Rotor, The Induction Machine with Solid. McConnell, Sverdrup....343–8; disc. 348

K

Kilovar Output of Large Capacitor Banks, Intermittently Increased. Minder....749–51; disc. 751

L

Laboratory, Capacitance-Switching Facilities at the Switchgear Development. Williams, Mankoff, Schneider....375–80; disc. 380
Levels of Magnetic Noise of Polyphase Induction Motors, Predetermination of Sound Pressure. Erdelyi....1269–80; disc. 1280
Life Evaluation of Group-2 Dry-Type Power Transformers, Functional. Zambell....956–70
Life Expectancy Tests for Liquid-Filled Distribution Transformers, Functional. Lockie....977–82; disc. 982
Life of Voltage-Regulating Relays, Contact. Schoendube, Elliott....1398–1400; disc. 1401
Life Tests of Insulation Systems for Dry-Type Transformers, Functional. Narbut....1057–61; disc. 1061
Lightning Arresters, Transient Durability Testing of Valve Type. Kalb, Yost....521–6; disc. 526
(Lightning) Direct-Strome Protection of High-Voltage Switching Stations and Transformers. Griscom, Dillard, Hileman....354–65; disc. 365
Lightning Protection in a 24-Kv Station—Field and Laboratory Studies. Armstrong, Ferguson, Hileman....1127–35; disc. 1135
(Limiter) A Mathematical Method for Determining Insulation Damage Curves for Network Cables. Kolks....934–8; disc. 944
(Limiter) Characteristic Properties of Secondary Network Cables. Rosch....939–44; disc. 944
(Limiter) Co-ordination of Secondary Network Protection. Leinbach, Brookes....922–4; disc. 944
(Limiter) High-Temperature Classification of Rubber and Rubberlike Insulation of Network Cable by Oven-Heating Tests. Couch, Crowdes....930–4; disc. 944
Limiter—Its Basic Functions in Network Distribution Systems, The. Xenis....913–15; disc. 944, 1463
(Limiter) Overload Classifications for Secondary Network Cables. Graham....916–19; disc. 944
(Limiter) Time Current Damage Characteristics, Cable in Duct. Porter....919–21; disc. 944
Limiters, Their Design Characteristics and Application. Heller, Matthysse....924–30; disc. 944, 1463
Lin-O-Phase Filter, Design of the Adjustable. Lee....273–7; disc. 277
Line and Transformer Bank Relaying Systems. Blackburn, Rockefeller....334–9; disc. 339
Line Constants With Tensors, ORACLE Computes. Shipley, Hochdorf, Watson....1052–6; disc. 1056
Lines Being Sleet-Melted by the Short-Circuit Method, Relay Protection for. Hogan, Pebler....1067–71; disc. 1072
Lines, Electromagnetic Unbalance of Untransposed Transmission. Gross, Nelson:
Part II....887–93
Liquid-Filled Distribution Transformers, Functional-Life Expectancy Tests for. Lockie....977–82; disc. 982
Load-Flow and Stability Equivalent for Power System Representation on A-C Network Analyzers, Combination. Brown, Cloues....782–6; disc. 786
Load Forecasting, Electric Utility. Godard....1428–40
Load Forecasting, The Application of Business Machines to Electrical Utility. Gruetter....854–8
Load Frequency Control System for Central Station Power, Automatic. Ehrenberg....787–95
Load-Phase Tie-Line Energy Control of Interconnected Power Systems. Cahen....1–5
Load Shedding, Automatic. (Committee Report)....1143–5; disc. 1145
Loads, Fundamental Relations of System Voltage Drop and System. Miller, Robbins....267–72; disc. 272
Location Methods, Bibliography and Summary of Fault. (Committee Report)....1423–7; disc. 1427
Loci of Salient-Pole Synchronous Motors: An Extension of Blondel Theory, Current. Douglas....1080–2; disc. 1082
Look to the Future of Power Transmission in the West, A. Hunkins....591–7; disc. 598
Loss Curves for Small Motors from Motor Tests, Developing Iron. Shaneman....1176–9
Loss Equation, A General Transmission. Early, Watson, Smith....510–16; disc. 516
Loss Equation, A New Method of Determining Constants for General Transmission. Early, Watson....1417–21; disc. 1421
Loss Formulas from Functions of Voltage Phase Angles, The Determination of Incremental and Total. Cahn....161–71; disc. 171
Losses in the Armature End Iron of Large Turbine Generators, Stray. Winchester....381–9; disc. 389
Low-Voltage Windings of Distribution Transformers, Impulse Tests on. Holcomb....1152–5; disc. 1155

M

Machine Transient Rotor Saliency on Changes in Terminal Voltage, Effect of Synchronous-. Concordia....25–31
Machine with Solid Iron Rotor, The Induction. McConnell, Sverdrup....343–8; disc. 348
Machines—Method for Short-Circuit Calculations, D-C. Cybulski, O'Connor....214–21
Machines: Response to Impact Excitation, D-C. Brockman, Linkous....500–03; disc. 503
Machines—Short-Circuit Calculations and Test Results, D-C. O'Connor, Cybulski....222–30; disc. 230
Machines to Electrical Utility Load Forecasting, The Application of Business. Gruetter....854–8
Machines, Two-Axis Method of Analyzing Electric. Tang, Cosgriff....1449–55
Magnetic Air Circuit Breaker Interrupters, Flux Measurements in. Carter....1062–5; disc. 1065
Magnetic Circuit Breaker of Simplified Design, A New 500-Megavolt-Ampere Air. Reilly, Weston....1093–8; disc. 1098
Magnetic Fields, Effect of Skew on Induction Motor. Linkous....760–5; disc. 765
Magnetic Noise of Polyphase Induction Motors, Predetermination of Sound Pressure Levels of. Erdelyi....1269–80; disc. 1280
Magnetization of Transformer Cores During Impulse Testing. Beavers, Holcomb, Leoni....118–23; disc. 123
Maintenance Practice of Philadelphia Electric Company, Turbine Generator Operation and. Gallagher....48–9
Manufacturer's Research in Relation to Electrical Utilities. Parker, Baird....557–06

Materials for Turbine Generators, Improved Field Conductor. Holley, Savidge..........72–6
Materials, High-Current Arc Erosion of Electric Contact. Wilson..........657–64; disc. 664
Mathematical Method for Determining Insulation Damage Curves for Network Cables, A. Kolks..........934–8; disc. 944, 1463
Maximum Short Circuit and Faulty Synchronizing Torques on Generator Foundations. Ruskin..........618–23; disc. 623
Measurement, Apparatus Noise. Wells..........1170–3
Measurement of Carrier Characteristics on Power Cables, A Method of. Sparlin, Moynihan...31–3
Measurement of Resistance and Reactance of Expanded ACSR. Tompkins, Jones, Tuttle..........368–73; disc. 373
Measurement of Resistance of Energized A-C Motor Windings. Waldschmidt......1303–04; disc. 1305
Measurements in Magnetic Air Circuit Breaker Interrupters, Flux. Carter.......1062–5; disc. 1065
Measurements on D-C Armatures, Correlation of Temperature. Gerbetz, Ewing...391–4; disc. 395
Mechanical Alignment of Vertical-Shaft Hydroelectric Units as Practiced by Tennessee Valley Authority. Norris..........586–9; disc. 589
Megavolt-Ampere Air Magnetic Circuit Breaker of Simplified Design, A New 500-. Reilly, Weston..........1093–8; disc. 1098
Metadyne Transients. Fegley..........1179–88
Metallic-Sheathed Cables, Mineral-Insulated. Jordan, Eager..........198–212; disc. 212
Method for Determining Economical ACSR Conductor Sizes for Distribution Systems, A. Funkhouser, Huber..........479–83; disc. 483
Method for Part-Winding Starting of Polyphase Motors, A New. Alger, Agacinsky.....1455–62; disc. 1462
Method for Short-Circuit Calculations, D-C Machines—. Cybulski, O'Connor..........214–21
Method for Studying Circuit Transient Recovery Voltage Characteristics of Electric Power Systems, A. Kotheimer..........1083–6; disc. 1086
Method for the Step-by-Step Calculations in Power System Transient Stability Studies, A Rational. Norinder..........1087–91; disc. 1091
Method of Analyzing Electric Machines, Two-Axis. Tang, Cosgriff..........1449–55
Method of Calculating Voltage Regulation Using Unit Impedance Power Reactive Diagrams, A Simplified. Butler..........304–10; disc. 310
Method of Determining Constants for the General Transmission Loss Equation, A New. Early, Watson..........1417–21; disc. 1421
Method of Measurement of Carrier Characteristics on Power Cables, A. Sparlin, Moynihan......31–3
Methods, Bibliography and Summary of Fault Location. (Committee Report).......... 1423–7; disc. 1427
Metropolitan Area, Operation of Turbine Generators During Off-Peak High Power Factor Periods—Practices of One Utility in a. Roberts, Webb..........461–5; disc. 466
Microwave Communications Systems, Recommendations for Improving Reliability of Stand-by Engine Generators for. Tharp..........261–6; disc. 266
Microwave System Parameters for Reliable Communications. Alvira, Corbell.......1100–07; disc. 1107
Mineral-Insulated Metallic-Sheathed Cables. Jordan, Eager..........198–212; disc. 212
Modern High-Voltage Rubber Insulation. Couch, Hunt, Kenney, Ware..........1387–97; disc. 1398
Motor Circuit, Weighted Mutual Reactances for a Triple-Cage. Martin..........765–8
Motor Magnetic Fields, Effect of Skew on Induction. Linkous..........760–5; disc. 765
Motor Noise Due to Dissymmetry Harmonics, Single-Phase Induction. Muster, Wolfert..........1365–72; disc. 1372
Motor, Ten Part-Winding Arrangements in Sample 4-Pole Induction. Courtin......1248–53; disc. 1253
Motor Testing, Application of Statistics to. Oldenkamp..........815–18; disc. 818
Motor Windings, Measurement of Resistance of Energized A-C. Waldschmidt.....1303–04; disc. 1305
Motors, A New Method for Part-Winding Starting of Polyphase Motors. Alger, Agacinsky..........1455–62; disc. 1462
Motors and Servomotors, Optimum Design of Induction Torque. Weiss..........809–15
Motors, Equivalent Circuit for the Concatenation of Induction. Ku..........1214–18; disc. 1219
Motors, Equivalent Circuits for Single-Phase. Slemon..........1335–42; disc. 1342
Motors from Motor Tests, Developing Iron Loss Curves for Small. Shaneman..........1176–9
Motors in Power Plants, Economic Selection of Auxiliary Drive. Gross, Bobrowicz.....1237–46; disc. 1246
Motors, Predetermination of Sound Pressure Levels of Magnetic Noise of Polyphase Induction. Erdelyi..........1269–80; disc. 1280
Motors Related to Slip Frequency, Vibration in 2-Pole Induction. Summers..........69–72
Motors, Sonance Design of Large Induction. Wall..........1189–92
Motors, The Transient Stalled Temperature Rise of Cast Aluminum Squirrel Cage Rotors for Induction. Rosenberry..........819–24, disc. 824
Multiplexing, Quadriphase—A New Approach to Time Division. Evans, Lowe..........900–03

N

Narrow-Band Frequency Modulated System, An Investigation of the Capture Effect in a. Hedges..........289–91; disc. 292
Network Analyzers, Combination Load-Flow and Stability Equivalent for Power System Representation on A-C. Brown, Cloues.....782–6; disc. 786
Network Cable by Oven Heating Tests, High Temperature Classification of Rubber and Rubberlike Insulation of. Couch, Crowdes..........930–4; disc. 944, 1463
Network Cables, A Mathematical Method for Determining Insulation Damage Curves for. Kolks..........934–8; disc. 944, 1463
Network Cables, Characteristic Properties of Secondary. Rosch..........939–44; disc. 944, 1463
Network Cables, Overload Classifications for Secondary. Graham..........916–19; disc. 944, 1463
Network Distribution Systems, The Limiter—Its Basic Functions in. Xenis......913–15; disc. 944, 1463
Network Impedances, Digital Calculation of. Glimn, Habermann, Henderson, Kirchmayer..........1285–95; disc. 1295
Network Protection, Co-ordination of Secondary. Leinbach, Brookes..........922-4; disc. 944, 1463
Network Systems, The Use of Probability in the Design and Operation of Secondary. Neagle, Nelson..........567–72; disc. 572
Network Vaults, Coincident-Outage Probability in Secondary-. Reps..........580–5; disc. 585
Networks, Basic Sequence. Kirschbaum.......771–4
New Method for Part-Winding Starting of Polyphase Motors, A. Alger, Agacinsky..1455–62; disc. 1462
New Method of Determining Constants for the General Transmission Loss Equation, A. Early, Watson..........1417–21; disc. 1421
Noise Control, Recent Contributions to Transformer Audible. Conover, Ringlee.......77–90; disc. 90
Noise Due to Dissymmetry Harmonics, Single-Phase Induction Motor. Muster, Wolfert..........1365–72; disc. 1372
Noise Measurement, Apparatus. Wells.......1170–3
Noise of Polyphase Induction Motors, Predetermination of Sound Pressure Levels of Magnetic. Erdelyi..........1269–80; disc. 1280
Noise on Power Lines, A Study of Carrier-Frequency. Moynihan, Sparlin:
  Part IV. Conclusion of Field Measurements..........795–800
Noise Tests on Large Power Transformers, An Anechoic Chamber for. Benoit, Hemmes, Schulz.....50–6
Nontension Aluminum Connectors. Boyer, Korges..........844–7; disc. 847
North Carolina, Development of Small Hydroelectric Sites in Western. Gnuse..........65–8
North Dakota, Bureau of Reclamation 230-Kv Transmission Lines in. Austin..........1147–51

Temperature Endurance Tests on a Silicone Glass Fiber Insulation System for Dry-Type Transformers, Functional. Manning.........91–8; disc. 98
Temperature Measurements on D-C Armatures, Correlation of. Gerbetz, Ewing.........391–4; disc. 395
Temperature Rise of Armature Windings, Some Factors Influencing the. Liwschitz-Garik.........752–9
Temperature Rise of Cast Aluminum Squirrel Cage Rotors for Induction Motors, The Transient Stalled. Rosenberry.........819–24; disc. 824
Temperature Transients, An Improved Approximate Technique for Calculating Cable. Van Wormer.........277–80; disc. 280
Temperatures at Various Hydrogen Pressures, Turbine Generator Stator Winding. Alger, Kilbourne, Snell.........232–50; disc. 250
Temperatures on Short Circuit, Transformer. Sealey.........1225–9; disc. 1229
Ten Part-Winding Arrangements in Sample 4-Pole Induction Motor. Courtin...1248–53; disc. 1253
Tennessee Valley Authority, Mechanical Alignment of Vertical-Shaft Hydroelectric Units as Practiced by. Norris.........586–9; disc. 589
Tension Calculations to Transmission Line Design, Practical Application of Sag and. Lummis, Fischer.........402–13; disc. 413
Tensors, ORACLE Computes Line Constants With. Shipley, Hochdorf, Watson.........1052–6; disc. 1056
Terminal Voltage, Effect of Synchronous-Machine Transient Rotor Saliency on Changes in. Concordia.........25–31
Test Circuits for Capacitance Switching Devices. Darrow, Phillips, Schultz, Shores.........624–34; disc. 634
Test Circuits, Testing of D-C Interrupters on A-C. Chen, Boehne.........1073–9; disc. 1079
Test Code for Functional Temperature Endurance Tests of Ventilated Dry-Type Power and Distribution Transformers, Proposed. (Committee Report).........971–5; disc. 975
Test Report on a Fully Supercharged Generator. Beckwith, Koetting, Rosenberg, Staats.........56–9
Testing, Application of Statistics to Motor. Oldenkamp.........815–18; disc. 818
Testing, Magnetization of Transformer Cores During Impulse. Beavers, Holcomb, Leoni.........118–23; disc. 123
Testing of Air-Disconnect Switches, High-Current. Gostin.........21–5
Testing of D-C Interrupters on A-C Test Circuits. Chen, Boehne.........1073–9; disc. 1079
Testing of Valve-Type Lightning Arresters, Transient Durability. Kalb, Yost.........521–6; disc. 526
Tests Concerning Circuit Breakers for Switching Long 230-Kv Lines, Design Problems and Field. Umphrey, Marsden.........693–701; disc. 701
Tests for Liquid Filled Distribution Transformers, Functional Life Expectancy. Lockie. 977–82; disc. 982
Tests Indicating the Concentration of Polar Compounds in Transformer Oil, Interpretation and Significance of. Johnson.........774–80; disc. 780
Tests of Insulation Systems for Dry-Type Transformers, Functional Life. Narbut.........1057–61; disc. 1061
Tests on a Silicone Glass Fiber Insulation System for Dry-Type Transformers, Functional Temperature Endurance. Manning.........91–8; disc. 98
Tests on Low-Voltage Windings of Distribution Transformers, Impulse. Holcomb.........1152–5; disc. 1155
Tests on 161-Kv Disconnecting Switches, Results of High-Current. McNerney.........104–08; disc. 108
Tests on Station Auxiliary Busses, Transfer. Backer, Barth, Huse, Taylor.........1441–5; disc. 1446
Theory of Dielectric Strength to Oil Circuit Breakers, Application of Volume. Wilson, Streater, Tuohy.........677–84; disc. 684
Thermal Relay and Its Application as a Cage Winding Protective Relay for Synchronous Machines, Improved Fast-Acting. Baude.........349–53; disc. 353
Thyrite Protection for Series Windings of Autotransformers. Albright.........150–4; disc. 154
Tie-Line Energy Control of Interconnected Power Systems, Load-Phase. Cahen.........1–5
Time/Current Characteristics of Cartridge Fuses With Single Wire Element, The Calculation of the Complete. Guile.........1108–15; disc. 1115
Time-Current Damage Characteristics, Cable in Duct. Porter.........919–21; disc. 944, 1463
Time Division Multiplexing, Quadriphase—A New Approach to. Evans, Lowe.........900–03
Torque Motors and Servomotors, Optimum Design of Induction. Weiss.........809–15
Torques on Generator Foundations, Maximum Short Circuit and Faulty Synchronizing. Ruskin.........618–23; disc. 623
Transductor-Type Field Ripple Detector for Synchronous Generators, A. McConnell.........476–9; disc. 479
Transfer of Steam-Electric Generating-Station Auxiliary Busses. Lewis, Marsh.........322–30; disc. 330
Transfer Tests on Station Auxiliary Busses. Backer, Barth, Huse, Taylor.........1441–5; disc. 1446
Transformer, An Experimental Gas-Insulated 138-Kv Current. Camilli.........100–03; disc. 103
Transformer Audible Noise Control, Recent Contributions to. Conover, Ringlee.........77–90; disc. 90
Transformer Bank Relaying Systems, Line and. Blackburn, Rockefeller.........334–9; disc. 339
Transformer Connections, Sequence Impedances of Symmetrical 3-Phase. Cogbill.........1313–23
Transformer Cores During Impulse Testing, Magnetization of. Beavers, Holcomb, Leoni.........118–23; disc. 123
Transformer Design, Control of Electrostatic Voltage Distribution in Power. Bennon, Cossaart.........1122–5; disc. 1125
Transformer Insulation, Evaluation and Application of Silicone-Organic Resin Combinations for Dry-Type. Simmons, Scheideler....155–60; disc. 160
Transformer Oil, Interpretation and Significance of Tests Indicating the Concentration of Polar Compounds in. Johnson.........774–80; disc. 780
Transformer Temperatures on Short Circuit. Sealey.........1225–9; disc. 1229
Transformer, The Forced Oil Cooled Rotary Welding. Shenk......... 873–80
Transformers, An Anechoic Chamber for Noise Tests on Large Power Power. Benoit, Hemmes, Schulz.50–6
Transformers, Direct-Stroke Protection of High-Voltage Switching Stations and. Griscom, Dillard, Hileman.........354–65; disc. 365
Transformers, Epoxy Resin Casting of Dry-Type Current. Farneth, Gallousis.........194–7; disc. 197

Load-Phase Tie-Line Energy Control of Interconnected Power Systems

FRANCOIS CAHEN
MEMBER AIEE

IN A previous paper[1] the author described the principle of an automatic control method based on the measurement of the integral of the deviation of the controlled quantity and upon the subjection to this integral of the load of the plants in control of the system. The method was more particularly applied in the case of a system which, although comprising a great number of generating stations, constitutes a single operation unit not interconnected to any other similar units. In this case, the quantity to be regulated is the frequency; the integral of the frequency deviation is a phase difference; the application of the method leads to subjecting the load of all the regulating machines to the value of this phase difference, hence the name load-phase control.

The advantages of this method permit an important decentralization of the control by utilizing several independent regulators distributed through the system and installed close to the power stations submitted to their action; the possibility of simultaneously operating several regulators quite independent of one another depends, as was shown, on the use of very accurate and very steady reference frequency generators. The regulators required for the application of this method have been studied and designed by Éléctricité de France and a certain number of tests carried out on the French system have shown, as stated in the previous paper, that this control process permitted both a very steady frequency maintained within a band of ±0.05 cycle per second and a very good distribution of the load among regulating plants without any manual intervention.

The author then pointed out that this control method could be extended to the case of several interconnected systems, each of which constitutes an operation unit; in such a case, however, the quantity to be regulated is no longer the frequency only but a combination of both the frequency and the power transferred between each system and all its neighbors according to the conventional frequency control with tie-line load-bias principle. It is then necessary to measure a linear combination of the frequency deviation and the tie-line load deviation in relation to the program, to integrate this combination which is transformed into a linear combination of a phase difference and tie-line energy difference, and then to subject the load of all the regulating machines to the value of this integral. That is why this process has been called load-phase tie-line energy control. Since that paper was presented, application tests of this method for those two cases have been and are being pursued on the French system; the aim of the present paper is to give a concise account of these tests.

New Tests and Industrial Application of the Load-Phase Control

New control tests have been made repeatedly on the French system in 1953 and 1954; they have confirmed results previously obtained, emphasizing the precision and flexibility of this control process. At the same time, the number of plants likely to take part in the control has been increased so as to make it possible to widen the control band. At the present time two independent integrating regulators are installed: one, in Paris, controls the steam plants of the Paris area and the other, in Brive, controls the hydroelectric plants of the Truyère and the Dordogne rivers in the Massif Central. The maximum capacity of the steam plants controlled by the first regulator is 875 megawatts (mw) (control band 250 mw); the maximum capacity of the hydroelectric plants controlled by the second regulator is 750 mw. A third regulator will be installed to control some hydroelectric plants in the Alps (maximum capacity 700 mw). As an indication, the maximum power supplied to the system by its power stations as a whole reached 8,000 mw in January 1954. In the periods when the French system can be isolated from the German system with which it is frequently interconnected, long deviation control tests are often being carried out.

Reminder of the Load-Phase Tie-Line Energy-Control Principle

The principle of this control method applicable to the case of several interconnected international systems has been mentioned in the foregoing. It is equivalent, in an integrated form, as stated in the previous paper,[1] to the conventional tie-line power and frequency control, the equation of which is

$$(P_t-P_0)+\lambda(f-f_0)=0$$

where

P_t = total power effectively transferred between the system and the other systems, mw
P_0 = transfer program, mw
f = effective value of frequency, cycles per second (cps)
f_0 = rated frequency, cps
λ = controlling energy of regulator

λ is expressed in mw per cycle or in an abridged form

$$\Delta f+\frac{\Delta P_t}{\lambda}=0 \tag{1}$$

where

$$\Delta f=f-f_0$$

$$\Delta P_t=P-P_0$$

The corresponding equation of the new method is

$$\alpha\int_0^t\left(\Delta f+\frac{\Delta P_t}{\lambda}\right)dt+\Delta p=0$$

or

$$\alpha\left(\Delta\varphi+\frac{\Delta W_t}{\lambda}\right)+\Delta p=0 \tag{2}$$

with

$$\Delta\varphi=\varphi-\varphi_0=\int_0^t \Delta f dt$$

where

φ = phase angle, revolutions
φ_0 = reference phase angle, revolutions

$$\Delta W_t=W_t-W_0=\int_0^t \Delta P_t dt$$

Paper 55-24, recommended by the AIEE System Engineering Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 13, 1954; made available for printing November 15, 1954.

FRANCOIS CAHEN is with Éléctricité de France, Paris, France.

The author wishes to thank Louis de Heem, Director of C.P.T.E., and the Belgian companies who own the power stations utilized for the tests for taking part in the load-phase tie-line energy-control tests and carrying out the necessary installations in Belgium. He also thanks Mr. Denis, Chief Engineer of the C.P.T.E., for the major part taken in carrying out these installations and in particular the control boards of the central dispatching office and of the power stations in control. Thanks are also due to André Chevallier, Éléctricité de France, who was mainly responsible for the creation and development of the automatic control methods based upon the measurement of the phase difference and the subjection to this difference of the load of the stations in control.

where

W_t = transferred energy, mw-seconds
W_0 = reference transferred energy, mw-seconds

$\Delta p_m = p_m - p_0$

where

p_m = effective power output of the plants in control, mw
p_0 = basic load of the plants in control, mw

φ_0, W_0, and p_0 are chosen so that

$$p_m = p_0 \text{ for } \left(\varphi + \frac{W_t}{\lambda}\right) = \left(\varphi_0 + \frac{W_0}{\lambda}\right)$$

or

$$\Delta\varphi + \frac{\Delta W_t}{\lambda} = 0$$

Fig. 1 shows the basic diagram of the regulator.

Of course, if several independent integrating regulators operating simultaneously in the same system are utilized, the power deviation ΔP_t measured at a central point must be transmitted by telemetering to all the regulators.

Load-Phase Tie-Line Energy-Control Tests

A certain number of tests have been made in the past year to develop this control method and study its efficiency. Its working may be considered at present to be quite satisfactory; it makes possible the simultaneous control both of the frequency common to two interconnected systems and the power transferred between those two systems with a precision

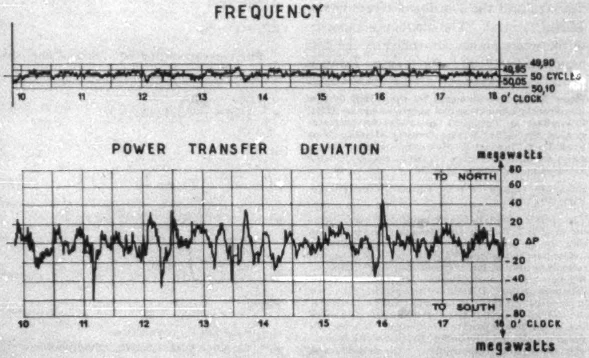

Fig. 2. Load-phase tie-line energy-control tests on June 29, 1954; frequency and power transfer deviation records

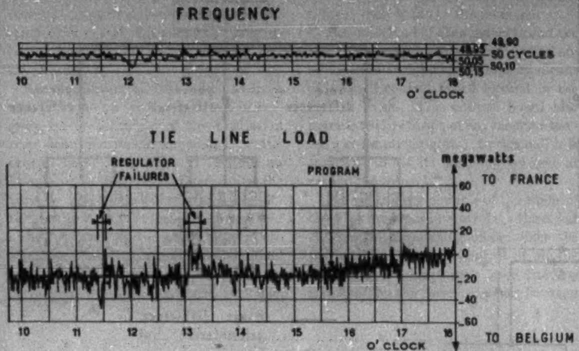

Fig. 4. Control tests on August 26, 1954; frequency and tie line load records

at least equal to that of the best conventional methods which do not utilize integrators. Moreover, within each of the systems, for the simultaneous putting under control of several power stations, advantages are offered for the balancing of their loads by the subjection of these stations to the integral of the deviation of the controlled quantity.

The essential aim of the first series of tests was the development of the load-frequency control device without paying too much attention to the problem of load distribution among the power stations in control, which the previous load-phase control tests permitted to consider as being solved. To this end, the French system has been divided into two parts, linked together by one or several 225-kv lines; on either side of the sham frontier, an integrating regulator acted upon several plants in control. The southern regulator controlled hydroelectric plants in the Massif Central, the northern regulator controlled steam plants located either in the north of France or in the Paris area. In the case when several 225-kv lines were utilized for interconnection, their loads were added together and the total compared with the program. The most recent test of this kind was made on June 29, 1954; the characteristics of this test are shown in Table I.

The test lasted from 10 a.m. to 6 p.m. Fig. 2 shows the recordings made of the frequency and of the deviation of the power transferred between the two systems in relation to the program.

The upper curve is that of the frequency; the latter was maintained throughout the test within the 49.95 to 50.05-cps band. The lower curve is that of the power deviation. Apart from extreme peaks (11:10 a.m., 12:05, 12:15, 12:25, 1:25, 1:45, 2:05, 3:50 and 4:00 p.m.) which result from modifications brought suddenly to the transfer program, it may be said that the power deviation in relation to the program has remained within a band having a width smaller than ±20 mw.

The aim of a second series of tests was to verify the smooth working of the control method, the latter being applied simultaneously to two interconnected systems, one of which utilized two distinct integrating regulators acting independently upon two groups of plants in control. For these tests, one of the systems was the Belgian system in which three distinct steam plants were controlled by a single integrator installed in Brussels at the central dispatching office of the Société pour la Coordination de la Production et du Transport de 'Élnergie Éléctrique. The other was the French system in which the two independent integrating regulators of Paris, controlling the Paris area steam plants, and of Brive, controlling the hydroelectric plants in the Massif Central, were operated simultaneously. A single 150-kv line was the interconnection link between the two systems; the load of this line was measured at the frontier and simultaneously transmitted by telemetering to Brussels and Paris. In Paris, this power was compared with the program and the measured deviation transmitted direct to the Paris regulator and telemetered to the Brive regulator. Fig. 3 shows schematically the geographic location of the regulators and the telemetering channels. The most recent test of this kind was made on August 26, 1954; the characteristics of this test are shown in Table II.

The test lasted from 9:46 a.m. to 5:42 p.m. Fig. 4 shows the recordings made of the frequency and of the power transferred between the two systems. Fig. 5 shows the load curves of the Belgian and French systems during the day of August 26. The upper curve is that of the frequency; the latter was maintained, for the duration of the test, within the 49.95 to 50.05-cps band, except about 12 o'clock when the deviation reached 0.1 cps because the control band of the French system, owing to unforeseen circum-

Fig. 7 (above). Utilization of a central integrator for one group of generating plants; direct subjection of the output of each machine to the phase difference, level control

stances, proved to be slightly insufficient.

The lower curve is that of the transferred power. The transfer program is shown by a thicker line; the difference of the ordinates of the two curves represents the power deviation. Apart from two short periods, at 11:30 a.m. and about 1:05 p.m., when a relay out of order temporarily disturbed the control, the power deviation in relation to the program remained within a band the width of which was smaller than ±20 mw.

Moreover, during this test, the load distribution among the plants in control of the French system, controlled by the independent integrating regulators of Paris and Brive, was carried out under excellent conditions in conformity with expectations. It was the same with regard to the load distribution between the three Belgian plants controlled by the Brussels integrating regulator under conditions which will be described in the following.

Subjection of Plants in Control to Integrating Regulators

As was stated in the previous paper,[1] the subjection of the output of the power stations in control to the integral of the difference of the controlled quantity, i.e., to the phase difference [$\Delta\varphi$ or $\Delta\varphi + (\Delta W_t)/\lambda$], may be achieved in different ways depending on the difference transmitted from the integrator near, more or less, to the regulating machines. Figs. 8, 9, and 10 of the previous report show schematically several instances of the working out of this subjection.

In the French system, the solution adopted so far consists in utilizing a central integrating regulator for each group of plants in control and in subjecting, on the spot, the total power supplied by these plants to the phase difference. This arrangement is schematically represented by Fig. 6. The regulator compares the total power of the plants with the phase difference and verifies whether these two values conform with the control characteristic sought. If agreement has not been reached, the regulator emits a signal proportional to the error it has measured; this signal is transmitted to the plants and, inside the latter, to the machines through distribution systems of a conventional type, securing the desired load distribution among the machines taking part in the control operations. This method has been utilized in the French system to take advantage of the existing installations of control signal transmission, of power totalization, and of signal distribution to the plants and machines. It has the disadvantage of requiring between the central regulator and the plants a double-link system transmitting in one direction the control signal and in the opposite direction the loads; moreover it makes it compulsory for the totalization of the latter to be made first at the plant, then at the central control station.

It is possible to eliminate any return power telemetering, any totalization, and any distribution devices by sending the value of the phase differences measured by a central integrator to all the plants in control and inside each of these to all the machines, and by subjecting separately the output of each of the machines to the phase difference by means of an individual regulator. This solution is schematically represented by Fig. 7. The individual regulator is a very simple device which makes the comparison between a voltage proportional to the phase difference and a voltage proportional to the difference between the power output of the machine and its basic load. When the law of subjection is fulfilled, the residual voltage is nil; when the law of subjection is no longer fulfilled, impulses of a duration proportional to the residual voltage drive the turbine speed-changing motor in the correct direction. This method has been called level control. The level is a current proportional to the phase difference; it is transmitted to all the regulating machines, the loads of which are subjected to it.

An installation of this kind has been experimented on for the first time in Belgium on the occasion of the regulation tests described in the foregoing. At the central dispatching office in Brussels an integrator is installed which emits the current, the intensity of which characterizes the level; the latter is transmitted either by wire, or by carrier current, to the three plants in control; the individual regulators of the machines, designed according to the aforementioned principle, subject their loads to the level.

The basic load of each machine and the rate of its participation in the control are adjusted in each power station by means of a small control board located in the control room. This control board also permits the operation of any machine having a constant program; to this end it is sufficient to set its participation rate at zero in the control.

The controlling power α of the whole of the power stations in control is adjusted at the central dispatching office; once the participation rates in control of all the regulating machines have been fixed, α is defined by the correspondence between the intensity of the current characterizing the level and the phase difference measured by the integrator. The tests of this method of subjecting the load of the power stations in control to the phase difference have been very satisfactory; its simple design and flexibility of utilization have been emphasized. Its application to the power stations in control of the French system is being contemplated.

Voltage Gradients on High-Voltage Transmission Lines

G. E. ADAMS
ASSOCIATE MEMBER AIEE

A KNOWLEDGE of the voltage gradient which exists at the surface of a transmission-line conductor is necessary in many instances. This knowledge is especially important in studies regarding corona losses and radio interference.[1-3] The dimensions of laboratory models of transmission lines are often chosen so as to reproduce the voltage gradient which is to be actually encountered in practice.[4] An indication of the electrostatic unbalance of a transmission line can also be gained from a knowledge of the voltage gradients. Results of such calculations of voltage gradients are presented here for several cases in the form of curves which make calculations unnecessary. These results are in agreement with the pertinent portions of two other papers which have appeared upon this subject.[5,6]

The arrangements for which data are included are: single conductor above ground, single circuit horizontal, single circuit vertical, and double circuit vertical. The effect of conductor diameter, conductor spacing, conductor height above ground, ground wires, and conductor stranding upon the voltage gradients can be determined from the curves presented.

The information is presented in the form of curves from which the gradient factor of a particular transmission-line arrangement can be obtained. This factor when multiplied by the voltage applied to the line yields the voltage gradient at the conductor surface. A wide range of the pertinent variables has been investigated and the voltage gradients of existing and proposed lines can be easily obtained from the curves.

Method of Analysis

The voltage gradient at the conductor surface was calculated in two steps. The gradient was calculated first of all as though the conductors were infinitely long, were suspended above a perfectly conducting flat ground plane, and had smooth cylindrical surfaces over which the charges were uniformly distributed. The interconductor and conductor to earth spacings were assumed to be constant and the effect of supporting structures, near-by objects, etc., was neglected. The details of this calculation are presented in the Appendix.

The results of this calculation are presented in terms of a gradient factor F_1 which is the ratio of voltage gradient to applied voltage. F_1 has the units of volts per centimeter (cm) per kilovolt of applied voltage. Since the voltage applied to the line varies sinusoidally with time, the charges and the voltage gradient also vary sinusoidally with time. F_1 has been expressed as the ratio of the peak volts per cm to the applied rms voltage. This applied voltage is to be taken as line to ground for a single conductor and line to line for 3-phase conductors.

The second step in the calculation was the determination of the ratio of the maximum voltage gradient at the conductor surface for a stranded conductor to the voltage gradient of a smooth conductor having the same outside diameter and the same charge. This ratio is expressed as a a strand factor F_2. The voltage gradient, of course, varies along the surface of a stranded conductor from zero at the points where the adjacent strands are in contact to a maximum at the points midway between. If it is assumed that the stranding does not change the capacitance[7] of the conductor appreciably, the

maximum gradient factor of a stranded conductor is given by $F = F_1 F_2$.

Results

Figs. 1, 2, and 3 and Tables I through VII show the dependence of the voltage gradient upon line arrangement. The gradient factor F_1 for a single conductor suspended at a height h feet above ground is given by Fig. 1 for a range of conductor diameters. This configuration is the one which is normally used for laboratory tests of conductors. This curve also gives the gradient factor for a conductor which is the inner member of a concentric cylinder arrangement. This latter configuration has also been used in laboratory tests of conductors.[6]

The charge, and consequently the voltage gradient, is uniformly distributed along the circumference of the conductor in the concentric cylinder arrangement. When the conductor is suspended above a flat ground plane, the charge becomes nonuniformly distributed over the surface. However, for values of h usually encountered in practice, this distortion of or deviation from a uniform distribution is less than 0.1 per cent (%) and may be neglected for all practical purposes.

Fig. 2 gives F_1 as a function of conductor diameter and spacing for the center conductor of a horizontal arrangement without ground wires. This set of curves was plotted for the particular case of height above ground h being equal to 60 feet. Table I shows a comparison of

values obtained for $h=60$ feet and $h=100$ feet. (See also Fig. 7(A) of reference 5.) Since the difference is very small, it can be concluded that Fig. 2 can be used for all values of h encountered in high-voltage practice. The height above ground becomes important only for abnormally small values of h. The voltage gradient is higher on the center than on the outer conductors. Table II gives the percentage difference between center and outer conductors as a function of conductor diameter and spacing. This difference varies as the ratio of conductor spacing to conductor dameter varies. The larger this ratio becomes, the smaller the difference.

Fig. 3 gives F_1 as a function of conductor diameter and spacing for the center conductor of a vertical arrangement without ground wires. The height of the center conductor or the average height of the conductors is taken as 60 feet. Table III shows a comparison between values for $h=60$ and $h=100$ feet. The difference is approximately twice as large as for the horizontal arrangement but still is very small and can be neglected for practical purposes for values of h and d encountered in practice. Since the upper and lower conductors are not at the same height above ground, the corresponding voltage gradients will not be equal. The voltage gradient on the bottom conductor will be larger than on the top conductor since it is closer to the ground. The center conductor, however, will have the largest voltage gradient except for extreme cases not usually encountered in practice when the lower conductor is very close to the ground. Table IV gives the percentage difference between center and upper and center and lower conductors. The minus signs indicate a gradient less than that of the center conductor.

Table V gives a comparison of horizontal and vertical arrangements without ground wires having the same average height above ground and the same spacing. The difference between gradient factors on the center conductors and between the average gradient factor of the three conductors is seen to be very small.

Table VI gives the gradient factor for the horizontal arrangement with ground wires as shown in Fig. 4. The radius of the ground wires r, the distance between ground wires $2l$, and the vertical distance between the plane of the ground wires and the plane of the conductors g was varied over a wide range. However, it is seen that the ground wire has little effect upon the gradient except when placed abnormally close to a conductor. In general, the ground wire increases the charge residing on and the voltage gradient of the nearest conductors and reduces the charge and gradient of conductors located further away. Hence ground wires placed near the outer conductors will tend to reduce the electrostatic unbalance of the line.[9] This reduction, however, is very small for practical spacings as is shown in Table VI.

Table VII gives the gradient factor F_1 of the ground wire itself for the horizontal arrangement. It is seen that the ground wire gradient factor is very small compared with that of the conductor unless the ground wire radius is unusually small and the ground wires are placed unusually close to the conductor.

Fig. 5 shows the strand factor F_2 as a function of the number of strands. This curve decreases from a value of $\pi/2$ for $n=2$ and approaches 1.40 as a close approximation as n becomes infinite.[10,11] Several intermediate values of n were investigated with the aid of a d-c board and yielded values close to 1.40. F_2 depends only upon the number of strands and not upon the diameter of the conductor. It can be seen from this curve that $F_2=1.40$ for nearly all conductors used in practice. Hence the maximum voltage gradient which exists at the surface of the conductor will be approximately 40% larger than the value calculated assuming a smooth conductor of the same outside diameter.

The voltage gradients of double-circuit transmission lines have also been con-

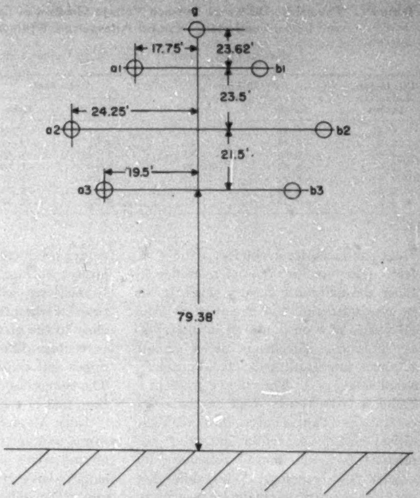

Fig. 6. Double-circuit arrangement, conductor diameter 1.6 inches

sidered. The equations to be solved are more complex than for single circuits although the method is the same. In addition, the gradients are affected by the choice of the conductor phasing. Different phasing arrangements result in appreciably different voltage gradients. If the exact voltage gradient on each conductor is desired, it is necessary to make a detailed analysis. However, for practical spacings a very close approximation to the gradient on the center conductors can be obtained by using either Figs. 2 or 3. The gradients on the upper and lower conductors are affected by the relative conductor phasing to a much larger degree than are those of the center conductors. Thus a calculation using Table IV might be a poor approximation. In general, the gradient is lower on the upper and lower conductors than on the center conductor.

The details of the calculations for the particular double-circuit arrangement shown in Fig. 6 are given in the Appendix. The voltage gradients of all seven conductors are given there for one particular set of instantaneous conductor voltages. If the voltage gradients are calculated for a range of values of time, the peak gradient on each conductor can be determined. This peak value of gradient, of course, occurs at a different time for each conductor.

The consideration of two particular phasing arrangements will serve to illustrate the general remarks made in the foregoing. Assume that balanced 3-phase voltages are applied to the double-circuit arrangement as given in Table VIII. The peak voltage gradients which result for $E=300$ kv line to line are also given. The gradients on the center conductors (*a2* and *b2*) differ from one another by less than 1/2 of 1%. Conductor phasing has little effect on the gradients of the center conductors. The average spacing *d* of this configuration is about 25 feet. The peak gradient factor as obtained from Fig. 2 for a 1.6-inch conductor is 70. For 300 kv, the peak voltage gradient thus obtained is 21,000 volts per cm as compared with the values in Table VIII. The double-circuit configuration affects the gradient of the center conductor by less than 1%. It is easily seen that the conductor phasing does effect the gradients of the upper and lower conductors considerably. The largest and smallest values of gradient shown differ by nearly 10%. The conductor phasing has a marked effect upon the ground wire gradient. However, even though the ground wire radius is small compared with the conductor radius, the ground wire gradient is very small compared with the conductor gradients.

Practical Applications

Fig. 7 gives the peak surface voltage gradient as a function of conductor diameter for various line-to-line voltages. The average height above ground was assumed to be 60 feet and the spacing 20 feet. While it is somewhat unrealistic to assume that the spacing does not vary with voltage, the curves shown were plotted from the preceding curves and serve to illustrate their use. The gradient was calculated using only the factor F_1.

If the maximum peak voltage gradient for a stranded conductor is desired, the values of gradient obtained from the curve should be multiplied by 1.40.

Fig. 8 gives for stranded conductors the values of rms line-to-line voltage which result in a maximum peak voltage gradient of 30,000 volts per cm on the center conductor as a function of conductor diameter and spacing. According to Peek,[12] when this "disruptive critical voltage" is reached corona losses occur. This voltage results in a "disruptive critical gradient" which is constant at about 30 kv per cm for wires and cables having radii larger than 0.20 cm. This curve shows that large single conductors are necessary for high-voltage operation if the maximum gradients are to be kept below 30,000 volts per cm.

Of course, the maximum voltage gradient is not the only important factor which influences corona discharges. The characteristics of the electric field in the space surrounding the conductor must be considered and are greatly influenced by the nature of the conductor surface. The nature of the conductor surface also affects the emission of electrons from the surface and secondary processes which are essential to the discharge. It should be remembered that, on the one hand, no conductor can be absolutely smooth, so that small sharp projections can increase the gradient beyond that calculated for either a smooth or stranded conductor, and therefore some discharge may exist at values of calculated gradient below the critical, and that, on the other hand, this discharge will itself affect the gradient, and will moreover contribute to the aging of the conductor. These factors tend to reduce the abrupt change which might otherwise be expected when the disruptive critical gradient is approached or exceeded.

Conclusions

1. The diameter of the conductor has the most significant effect upon the surface voltage gradient for practical arrangements. An increase of conductor diameter decreases the voltage gradient. Since the charge for a given voltage increases with increasing diameter, the per-cent decrease in gradient will be somewhat smaller than the per-cent increase in diameter. The gradient will decrease about 0.8% for every 1% increase in conductor diameter.

2. The conductor spacing has the second largest effect upon the voltage gradient. The gradient increases as the spacing is reduced.

3. The height above ground has very

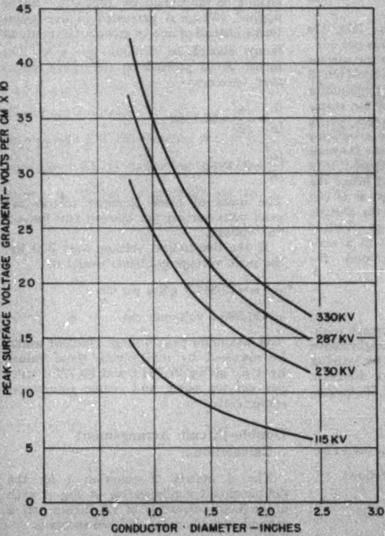

Fig. 7 (left). Variation of the peak surface voltage gradient on the center conductor of a horizontal arrangement with line-to-line applied voltage for a height above ground of 60 feet and a spacing of 20 feet

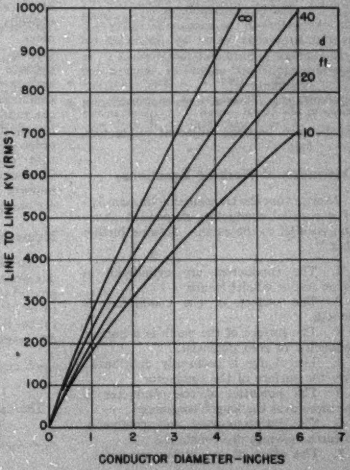
Fig. 8 (right). Variation of the disruptive critical voltage with conductor diameter and spacing for a stranded-conductor, single-circuit horizontal or vertical arrangement



little effect upon the voltage gradient for practical arrangements.

4. Ground wires have very little effect upon the voltage gradient for conventional spacings.

5. For the stranded conductors in use today (having 20 or more outer strands), the maximum surface voltage gradient is approximately 40% larger than that calculated on the basis of a smooth conductor of the same outside diameter.

6. For the same conductor spacing and radius, the voltage gradient of the center conductor and the average voltage gradient for a horizontal configuration is only slightly different from the respective gradient of a vertical configuration of the same average height above ground.

7. The center conductor has the largest voltage gradient for all commonly used configurations.

8. For spacings and diameters of ground wires in common use, the ground wire gradients are very low as compared with those of the phase conductors.

9. The curves contained herein can also be used to obtain the voltage gradient on the center conductor of a double-circuit arrangement to a close approximation.

10. The electrostatic unbalance of a transmission line becomes less as the conductor spacing is increased. For practical spacings, ground wires reduce the unbalance very slightly.

Appendix. Calculation of Voltage Gradient

Nomenclature

h_n = height of conductor n above ground, feet
R_n = radius of conductor n, feet
r_{nm} = distance between actual conductors n and m
r_{nm}' = distance between actual conductor n and image conductor m'
Ln = logarithm to the base $\epsilon = 2.71828$
e_n = instantaneous value of potential between ground and conductor n
q_n = instantaneous value of charge on conductor n
ϵ_n = voltage gradient at surface of conductor n
d = distance between adjacent conductors, feet

Derivation of Working Equations

Assume that the transmission line consists of n parallel conductors suspended above and parallel to the earth. Assume further that:[13]

1. The conductors are cylindrical in shape and of infinite length.
2. The surface of the conductors is smooth.
3. The surface of the earth is a perfect conductor of zero potential.
4. The charge is uniformly distributed over the surface of the conductor.
5. The potential of the conductor is the same over the length considered.
6. The interconductor and conductor to earth spacings are constant.
7. The effect of supporting structures, near-by objects, and the character of the soil is neglected.

It is well known[14] that this system of conductors and ground can be replaced by an equivalent system composed of the actual conductors plus image conductors all of which are suspended in free space.

The voltages from ground to the conductors are related to the charges on the conductors by Maxwell's coefficients of capacitance.[14] The equations are then

$$\begin{aligned} e_1 &= A_{11}q_1 + A_{12}q_2 + \ldots + A_{1n}q_n \\ e_2 &= A_{21}q_1 + A_{22}q_2 + \ldots + A_{2n}q_n \\ e_n &= A_{n1}q_1 + A_{n2}q_2 + \ldots + A_{nn}q_n \end{aligned} \qquad (1)$$

where

$$A_{nn} = 2\text{Ln}\,\frac{2h_d}{R_n}$$

$$A_{nm} = 2\text{Ln}\,\frac{r_{nm}'}{r_{nm}}$$

When these equations are inverted, the charges are obtained as functions of the applied voltages. The equations become

$$\begin{aligned} q_1 &= B_{11}e_1 + B_{12}e_2 + \ldots + B_{1n}e_n \\ q_2 &= B_{21}e_1 + B_{22}e_2 + \ldots + B_{2n}e_n \\ q_n &= B_{n1}e_1 + B_{n2}e_2 + \ldots + B_{nn}e_n \end{aligned} \qquad (2)$$

Equations 2 are expressed in centimeter-gram-second units. If the applied voltages are expressed in statvolts, the charges obtained from equation 2 will be expressed in statcoulombs per cm of conductor length. If the charge is assumed to be uniformly distributed around the conductor, the electric flux leaving the conductor will be in a radial direction and $4\pi q$ lines per cm of conductor length in magnitude. The electric field intensity perpendicular to the conductor surface or voltage gradient is then given by

$$\epsilon_R = 2\frac{q}{R} \text{ statvolts per cm} \qquad (3)$$

If equation 3 is multiplied by 300, the gradient will be expressed in volts per cm.

The electric field intensity at the surface of a conductor as given by equation 3 depends upon the charge on that conductor alone. The other conductors of the transmission system also have charges which produce an electric field at the conductor surface. However, the distances between conductors are very large compared with the radius of the conductor and hence the electric field of the other charges is of the order of 1/2 of 1% or less of the electric field of the conductor charge itself.[5,6] This second-order effect results in a nonuniform electric intensity around the periphery of the conductor.

Numerical Example

Consider a horizontal arrangement without ground wires. Assume the height above ground to be 30 feet, the conductor spacing to be 16 feet, and the conductor diameter to be 0.1466 foot or about 1.76 inches. Also assume that

$$e_1 = E\cos\omega t,\; e_2 = E\cos(\omega t - 120),\; e_3 = E\cos(\omega t + 120)$$

The calculations proceed as follows

$$A_{11} = A_{22} = A_{33} = 2\text{Ln}\,\frac{60}{0.0733} = 13.4105$$

$$A_{12} = 2\text{Ln}\,\sqrt{1 + 4\left(\frac{30}{16}\right)^2} = 2.71216$$

$$A_{13} = 2\text{Ln}\,\sqrt{1 + \left(\frac{30}{16}\right)^2} = 1.50753$$

$$B_{11} = B_{33} = 0.0781541$$

$$B_{22} = 0.0804556$$

$$B_{12} = B_{23} = -0.0146227$$

$$B_{13} = -0.00582631$$

$$\frac{q_1}{E} = 0.0883786\cos\omega t - 0.00761788\sin\omega t$$

$$\frac{q_2}{E} = -0.0475392\cos\omega t + 0.0823402\sin\omega t$$

$$\frac{q_3}{E} = -0.0375920\cos\omega t - 0.0803470\sin\omega t$$

$$\left|\frac{q_1}{E}\right| = 0.0887010 \text{ statcoulomb per statvolt}$$

$$\left|\frac{q_2}{E}\right| = 0.0950730 \text{ statcoulomb per statvolt}$$

$$\left|\frac{q_3}{E}\right| = 0.0887010 \text{ statcoulomb per statvolt}$$

$$\left|\frac{\epsilon_1}{E}\right| = \left|\frac{\epsilon_3}{E}\right| = 0.0810135 \text{ statvolt per cm per statvolt}$$

$$\left|\frac{\epsilon_2}{E}\right| = 0.0868332 \text{ statvolt per cm per statvolt}$$

The units of the latter two quantities are obviously also volts per cm per volt. If the peak voltage gradient factor is desired, but it is more convenient to use rms values of applied voltage expressed in kilovolts, the gradient factors just given should be multiplied by $1000\sqrt{2}$. If the applied voltage is expressed in line-to-line terms instead of line to ground, the gradient factor should be divided by $\sqrt{3}$. The factor F_1 as plotted on the curve sheets then becomes

$$\left|\frac{\epsilon_1}{E}\right| = \left|\frac{\epsilon_3}{E}\right| = 66.1468$$

$$\left|\frac{\epsilon_2}{E}\right| = 70.8986$$

The units of these gradient factors are peak volts per cm per kilovolt rms line-to-line voltage.

If the line-to-line voltage were 300 kv, the peak voltage gradients would be

$\epsilon_1 = \epsilon_3 = 19{,}844.0$ volts per cm

$\epsilon_2 = 21{,}269.6$ volts per cm

The maximum peak voltage gradient would be obtained by multiplying these values by 1.40, giving 27,781.6 and 29,777.4 volts per cm for outer and center conductors respectively.

Double-Circuit Arrangement Calculations

The A matrix of equation 1 for the double-circuit configuration of Fig. 6 with a conductor diameter of 1.6 inches and a ground wire diameter of 0.576 inches is

	$a1$	$a2$	$a3$	$b1$	$b2$	$b3$	g
$a1$	16.449	4.4476	3.0195	3.9141	3.1210	2.5365	4.4467
$a2$	4.4476	16.030	4.2008	3.1210	2.9072	2.6813	3.1030
$a3$	3.0195	4.2008	15.551	2.5365	2.6813	2.8906	2.3273
$A=b1$	3.9141	3.1210	2.5365	16.449	4.4476	3.0195	4.4467
$b2$	3.1210	2.9072	2.6813	4.4476	16.030	4.2008	3.1210
$b3$	2.5365	2.6813	2.8906	3.0195	4.2008	15.551	2.3273
g	4.4467	3.1030	2.3273	4.4467	3.1210	2.3273	18.839

The inverse of the A or the B matrix of equation 2 is

	$a1$	$a2$	$a3$	$b1$	$b2$	$b3$	g
$a1$	0.071939	−0.013096	−0.0058169	−0.0087569	−0.0051853	−0.0036882	−0.010728
$a2$	−0.013096	0.073272	−0.013975	−0.0051853	−0.0047792	−0.0049088	−0.0046336
$a3$	−0.0058169	−0.013975	0.072481	−0.0036882	−0.0049088	−0.0076756	−0.0026521
$B=b1$	−0.0087569	−0.0051853	−0.0036882	0.071939	−0.013096	−0.0058169	−0.010728
$b2$	−0.0051853	−0.0047792	−0.0049088	−0.013096	0.073272	−0.013975	−0.0046336
$b3$	−0.0036882	−0.0049088	−0.0076756	−0.0058169	−0.013975	0.072481	−0.0026521
g	−0.010728	−0.0046336	−0.0026521	−0.010728	−0.0046336	−0.0026521	0.060328

As an example take:

$e_{a1}=e_{b1}=E\cos\omega t$

$e_{a2}=e_{b2}=E\cos(\omega t-120)$

$e_{a3}=e_{b3}=E\cos(\omega t+120)$

$e_g=0$

For 300-kv rms line-to-line voltage

$$E=\frac{300{,}000\sqrt{2}}{\sqrt{3}}=244{,}950 \text{ volts}=816.50 \text{ statvolts}$$

For $\omega t=0$

$a1$	816.50
$a2$	−408.25
$a3$	−408.25
$e=b1$	816.50
$b2$	−408.25
$b3$	−408.25
g	0.0000

Then from $q=Be$

$q_{a1}=q_{b1}=62.932$ statcoulombs per cm

$q_{a2}=q_{b2}=-35.180$ statcoulombs per cm

$q_{a3}=q_{b3}=-26.509$ statcoulombs per cm

$q_g=-11.570$ statcoulombs per cm

From $\epsilon=2(q/R)$, the electric intensities are

$\epsilon_{a1}=\epsilon_{b1}=62.002$ statvolts per cm $=$ 18,600 volts per cm

$\epsilon_{a2}=\epsilon_{b2}=-34.660$ statvolts per cm $=$ −10,398 volts per cm

$\epsilon_{a3}=\epsilon_{b3}=-26.117$ statvolts per cm $=$ −9,484 volts per cm

The calculations were carried out with the aid of an International Business Machines card programmed calculator. The availability of this machine made the collection of the foregoing results practical since it can solve the number of equations involved in a reasonable length of time.

Oscillations of Coupled Windings

Synopsis: The oscillations of a single winding have been extensively investigated, but actually the most important practical case, the oscillations of coupled windings, has received but scant attention. The wave shapes and natural frequencies are determined in this paper for two coupled windings of any turn ratio and with the same or opposite winding direction, in air or on an iron core. The integral equation and the equivalent circuit methods, previously developed for single windings, are extended to introduce the effect of the secondary on the primary, and then to investigate various winding combinations of turns ratio varying from 1 to 1 to 1 to 9. Good agreement is found between computed and measured values of the natural frequencies and wave shapes.

EXTENSIVE theoretical and experimental investigations of the oscillations of single windings, in air or on an iron core, have been made in the past. To take into account completely and rigorously all mutual inductance linkages between all the turns, previously neglected, two of the authors have developed the equivalent circuit method[1] and the integral equation method.[2] The first method yielded all the natural frequencies of practical importance, but not the wave shapes; while the second gave both wave shapes and natural frequencies, but only for the fundamental oscillation. In both cases excellent agreement was obtained between calculations and measurements made on an experimental coil with air core or iron core, whose parameters could be varied over a wide range.

Knowledge of the normal functions of single windings is of fundamental importance for the determination of the response to impulse voltages and switching surges of air coils, iron-core coils, reactors, and generator windings. The most important practical application, however, concerns the behavior of transformer windings subjected to lightning, commercial impulse tests, and switching surges. Since transformers have at least two windings, and often more, it is astonishing that so little attention has been given in the literature to the oscillations of coupled windings. Bewley[3] investigated more than 20 years ago the transient oscillations of mutually coupled windings, and later Boyajian[4] and Vitins[5] the special case of an oscillating high-voltage secondary. All these authors assume that the wave shapes of the normal functions (or standing waves) are sinusoidal. It has been shown recently[2] from the solution of the integral equation, and confirmed by an extensive series of tests, that the normal functions of a single winding are not sinusoidal, and there is no reason to believe that the presence of another winding would alter this conclusion. Furthermore, Boyajian and Vitins neglected altogether the capacitances of the low-voltage winding and its oscillations.

Results obtained for single windings are generally used for transformers, and the mutual effect of the two windings is neglected altogether. In many practical cases this approximation yields astonishingly satisfactory results, but a theoretical justification is lacking, as well as the establishment of the limits within which it is valid. For these reasons, methods used for the analysis of oscillating single windings were extended, first to study the effect of the secondary winding on the primary oscillations and neglecting the less important secondary oscillations and, second, to analyze the oscillations of a system of two coupled windings, wherein both windings are considered on the same basis.

Effect of the Secondary on the Mutual Inductance Function of the Primary

First consider only the effect of the secondary winding on the fundamental oscillation of the primary. It will be assumed that:

1. Both windings are uniform.
2. The number of turns in the primary is much greater than the number of turns of the secondary.
3. The capacitance from secondary to ground is much larger than the sum of the capacitances from primary to secondary and from primary to ground, in parallel.
4. Primary and secondary series capacitances can be neglected.

The last assumption follows from the fact that we are considering only the fundamental oscillation of the primary and that series capacitance affects appreciably only the higher harmonics.[2-4] Assumptions 2 and 3 allow the conclusion that while the primary winding is oscillating there will not be any appreciable voltage transferred by electromagnetic or electrostatic induction to the secondary which, therefore, will always remain at ground potential.

Let $M(x,s)dxds$ be the mutual inductance of two elements of the primary winding located at points of abscissas x and s from one end of the winding, referred to the length of the winding taken as unity. If there is no secondary winding, this mutual inductance function[1] $M(x,s)$ can be assumed both for air-core and iron-core coils to be a function only of the distance $|x-s|$ between the two elements, and not of x and s separately. This leads to a discussion of the secondary winding and the study of its effects on the mutual inductance function. As long as the secondary is open-circuited no current can flow in it, and the function

Paper 55-29, recommended by the AIEE Transformers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 19, 1954; made available for printing November 16, 1954.

P. A. ABETTI is with the General Electric Company, Pittsfield, Mass., and G. E. ADAMS and F. J. MAGINNISS are with the General Electric Company, Schenectady, N. Y.

All measurements were made by the staff of the High Voltage Engineering Laboratory of the General Electric Company, Pittsfield, Mass.

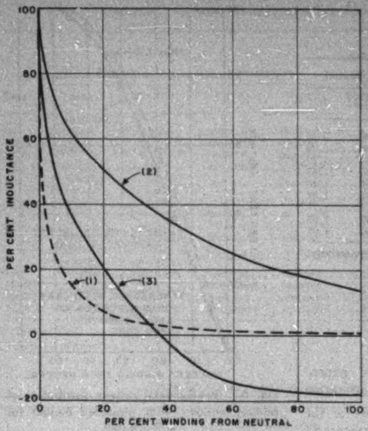

Fig. 2 (left). Mutual inductance function at ends of an experimental coil. Same designations as for Fig. 1

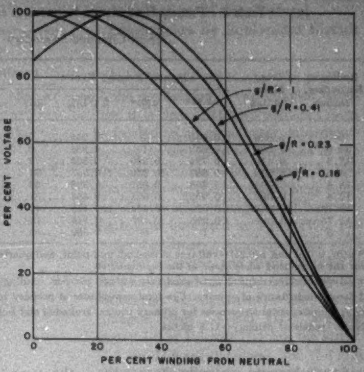

Fig. 4 (right). Fundamental voltage distributions of primary winding with isolated neutral for large values of g/R = (gap/average radius), short-circuited secondary

$M(x,s)$ is not affected. However, if the secondary is short-circuited the current flowing in it will completely change the flux pattern and thus the function $M(x,s)$. Furthermore, it is clear that now the mutual inductance between two primary turns will depend not only upon their distance, but also upon their location. Thus $M(x,s)$ is a function of both coordinates x and s. It is interesting to note that within certain regions the function $M(x,s)$ will take negative values. Figs. 1 and 2 show the function $M(x,s)$ at the center and at either end respectively of an experimental coil[1,2] for the following conditions: 1. With air core, secondary absent or open-circuited. 2. With iron core, secondary absent or open-circuited. 3. With short-circuited secondary, with iron core. These curves were computed from Grover's tables[6] and found to agree well with measurements. Similar results have been obtained by Karasev and Sklyanin.[7] It is seen that corresponding curves in Figs. 1 and 2 have different shape only for case 3, since both windings are uniform. To facilitate comparison, the maximum value, which is the self-inductance of a single turn, is taken as unity for all cases, and the actual values are given in Table I.

Table I. Self-Inductance of Single Turn of Experimental Coil

Case	Inductance, Microhenrys	
	At Center	At Ends
1, Open-circuited secondary, air core	2.66	2.66
2, Open-circuited secondary, iron core	3.50	3.61
3, Short-circuited secondary, iron core	1.83	2.84
4, Copper screen, air core and iron core	1.80	1.80

It should be mentioned at this point that when a metal screen such as a copper cylinder is substituted for the secondary winding, the mutual inductance function is not the same as with short-circuited secondary. In fact Fig. 1 shows that the function $M(x,s)$ with a screen, curve 4, decays much faster than for any other case and does not take negative values. The presence of the screen reduces the amount of mutual flux below the air-core value. Thus a coil with a short-circuited screen, with air core or iron core, behaves just as an air-core coil of much larger equivalent length to diameter ratio.[1] Therefore, in general, it is not permissible to substitute a metal screen for the secondary in the theoretical and experimental investigation of transformer transients. This confirms the results of a previous investigation by field theory.[8]

It may be concluded that when the secondary is short-circuited and the stated assumptions are valid, the primary winding can be treated as a single nonuniform winding with a self-inductance function[1]

$$L_0(x, s) = \int_0^x \int_0^s M(\xi, \sigma) d\xi d\sigma \qquad (1)$$

The integral equation method previously used[2] for nonuniform windings without secondary may also be used for uniform windings with short-circuited secondary.

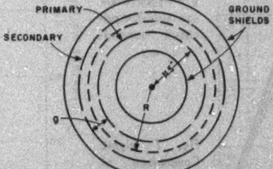

Fig. 3. Concentric windings. R = average radius, g = gap. Both windings 48 inches high

Effect of the Short-Circuited Secondary on the Fundamental Oscillations of the Primary

For the calculation of the fundamental oscillations, the 1,800-turn winding previously described[2] was considered to be the primary. Various secondaries were assumed to be located concentrically outside the primary (Fig. 3) and the ratio g/R of the gap g between primary and secondary to their average radius R was varied between wide limits, encompassing the geometry of 2-winding transformers with concentric windings. Calculations were made of the fundamental wave shapes and frequencies for the two most important primary terminal conditions: for 1. both ends grounded, and 2. line end grounded, neutral end isolated (obviously the role of the two ends is interchangeable because of symmetry). The results are summarized in Table II and in Figs. 4, 5, and 7 for isolated neutral; in Fig. 6 for grounded neutral. When the secondary winding has a much greater radius than the primary, its effect is negligible and the same results are obtained as for the primary alone in air (case 1 in Table I of reference 1).

First, consider the case of primary neutral isolated. As the short-circuited sec-

* u(0), u(0.5) and u(0.25) = voltages at neutral, mid-point, and quarter-points of the winding respectively, for the normalized wave shape of the fundamental.

† x_m = abscissa corresponding to maximum voltage, per-cent winding from neutral.

‡ L = self-inductance of primary; C_g = total capacitance of primary to ground.

f_g, f_i = fundamental frequencies for primary neutral grounded and isolated respectively.

Note: radius of primary = 11.5 inches.

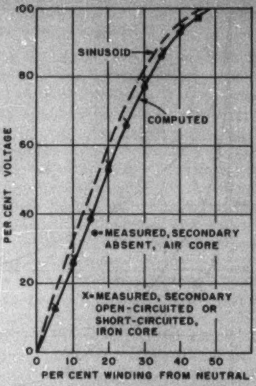

Fig. 6. Fundamental voltage distribution of primary winding with grounded neutral for g/R = 0.083

ondary is brought gradually closer to the primary, its effects are felt more and more. The voltage distribution becomes more peaked, the maximum voltage is found no more at the neutral end and the abscissa of the point with maximum voltage gradually approaches the mid-point of the winding (Figs. 4 and 5). At the same time the fundamental frequency with isolated neutral increases over a range equal to 2.31, the ratio of the fundamental frequencies with grounded and isolated neutral when the secondary is absent. These results are independent of turn ratio and relative winding directions. Usual values of the ratio g/R in power transformers vary between 0.2 and 0.04, so that the voltage distribution is by no means cosinusoidal, as generally assumed in the literature. As the gap is reduced to zero and the short-circuited secondary coincides with the primary, the fundamental voltage distribution is the same as if the primary neutral were grounded, because of the perfect coupling between the two windings. (This limiting case is the same as case 1 of Vitins' paper,[5] where the value 0.5 is obtained rather than 0.580 for $f_i\sqrt{L\ C_g}$ because of the simplifying assumptions with respect to the mutual inductance function.)

Now, in the case of primary neutral grounded, it is noted from Table II and Fig. 6 the surprising fact that when our initial assumptions are valid the secondary has no effect whatever on the fundamental oscillation of the primary. The minute differences in the values of $u(0.25)$ and of $f_g\sqrt{L\ C_g}$ are probably the result of slight inaccuracies in the evaluation of the kernels of the integral equation and in the iterative solution of this equation by means of digital computers. The physical explanation of this interesting fact is that, because of the symmetry with respect to the mid-point of the current distribution along the primary winding grounded at both ends, the sum of the ampere turns is always zero. Thus the sum of the flux linkages of the secondary winding is zero and no voltage can be measured between its open-circuited terminals. It will make no difference therefore whether these terminals are isolated or connected together. Since almost all high-voltage power transformers have the primary neutral grounded, and our initial assumptions are at least approximately valid for the majority of cases, this explains the hitherto unexplained fact that a circuit which "ignores the presence of the secondary circuits...strangely enough proves quite adequate to describe the internal high-frequency transients of the winding under consideration, not only qualitatively, but quantitatively as well."[3]

With secondary absent or open-circuited, or with a metallic screen, the ratio of f_g/f_i of the fundamental frequencies with grounded and isolated neutral can vary between 2 and very large values.[2] Values of about 2 are usually ob-

Table IV. Description of Secondary Windings

TC No.	Core	Secondary Turns	Turn Ratio	Self-inductance, Microhenrys		Capacitance Values, Micromicrofarads, 5-Element Representation				
				L_{pp}	L_{ss}	C_{pp}	C_{ss}	C_{pg}	C_{ps}	C_{sg}
6	Air	200	9.00	86.8	1.32	5.0	23.5	32.0	248	236
7	Air	704	2.56	86.8	15.0	5.0	6.3	32.0	248	250
8	Air	1800	1.00	86.8	99.7	5.0	5.0	32.0	248	236
9	Iron	210	8.57	305.0	4.16	5.0	23.5	32.0	248	236
10	Iron	1800	1.00	305.0	317.5	5.0	5.0	32.0	248	236

tained with a screen, values of 2.2 to 2.9 for air coils, of 5 to 12 for power and distribution transformers. It is found that when the secondary is short-circuited this ratio will always be less than when the secondary is absent or open-circuited, and that for power transformers it will vary between 1.1 to 1.6. Since the leakage flux is essentially in air, it will make no difference whether both windings are in air or on an iron core. The self-inductance function was computed for the two windings in air, and Fig. 6 shows that the computed distribution for $g/R=0.083$ and primary neutral grounded is in excellent agreement with the distribution measured on the same windings (1,800-turn primary, 210-turn secondary), first in air and then on an iron core. The computed values of f_g, f_i (in KC) and f_g/f_i for this case are 19.0, 15.0, and 1.27 respectively; and the measured values 19.5, 15.5, 1.26 respectively. Measured and computed distributions with primary neutral isolated for the same ratio of g to R, but with an 1,800-turn secondary and iron core, are compared in Fig. 7. There is a general agreement in the wave shapes and in the neutral voltages (computed and measured values both 62 per cent (%) of maximum) and the differences result from the 1-to-1 turn ratio, which does not agree with the initial assumptions. The general conclusions obtained here concerning the ratio of the fundamental frequencies agree well with tests made on eight power transformers, ranging from 500 to 20,000 kva per phase. The measured frequency ratio f_g/f_i varied between 5.7 and 10.5 when the secondary was open-circuited, and between 1.11 and 1.62 when the secondary was short-circuited. Similar experimental results have been obtained by Karasev and Sklyanin[7] with two windings on an iron core. The measured frequency ratios were 7.3, 1.26, and 2.15 respectively for open-circuited secondary, short-circuited secondary, and secondary replaced by a copper screen. These values also agree very well with the theory presented here.

Determination of the Natural Frequencies by Equivalent Circuit

For a general solution of the problem of the oscillations of two coupled windings, it is clear that both windings must be treated on an equal basis, subordinating one to the other as was done in the previous section. The problem is also complicated by the fact that a large number of terminal conditions must be investigated, as indicated in Table III. Because of symmetry some conditions yield identical solutions, and when the roles of the primary and secondary (arbitrary but convenient designations) are interchanged, cases I-4 and III-1, are the same; I-2 or I-3 and II-1 are the same; II-2 and II-3 are the same; and II-4 and III-2 or III-3 are the same, so that six different conditions must be investigated analytically. This number should be doubled since the two windings can be wound in the same or in the opposite direction, but it will be sufficient to define all mutual inductances as numbers with their own signs, which will all be positive or negative depending on the relative winding directions. It will be shown that another terminal condition, that of secondary short-circuited but isolated from ground, can be derived from two of the six conditions just discussed.

The equivalent circuit method[1] has been extended to determine the natural frequencies of an arbitrary number of coupled windings, and will be explained for the case of transformers with two concentric windings. First, each winding must be subdivided into a number of elements, and the degree of accuracy of the natural frequencies will depend upon the number of elements used. For this investigation it was desired to calculate the fundamental frequency with at least 10% accuracy, and the second and third harmonic frequencies with at least 20% accuracy, and thus five elements were

§ Measured.

chosen to represent each winding. As previously, mutual inductances were included between each element and every other element, as well as the series and shunt capacitances of both windings.

For simplicity, the equations will be set up for a 2-element representation of each winding, as in Fig. 8. Subscript *p* refers to the primary, *s* to the secondary and *g* to ground, represented by the core and the tank. The equations describing the circuit of Fig. 8 can be written more simply on the nodal basis than on the loop basis. In fact, the system consists of 7 nodes, 17 elements, and 1 separate part: hence the number of independent node pairs if 6, while the number of independent loops is 11. The nodal equations for the system of Fig. 2 are derived in the Appendix and are easily adapted to the various terminal conditions. If a terminal is grounded, the corresponding voltage is set equal to zero and the corresponding nodal equation is no longer valid and hence is disregarded. For instance, if terminal *pa* is grounded, V_{pa} is zero and the first column and first row in the impedance matrix 11 of the Appendix are eliminated. Therefore the number of required equations depends upon the terminal conditions and is listed in Table III.

During the free oscillations of this system of coupled windings, a finite set of voltages will satisfy the equations only if the determinant of the impedance matrix is zero. This will happen for discrete values of the frequency ω, which are the natural frequencies of the system. Since the order of the determinant is equal to the number of equations, 2 to 6 for this simplest case, and 8 to 12 for the 5-element representation, the calculations can be done only with modern digital computers. Even so, the calculations become quite laborious as the order of the determinant increases and it is important to reduce the system of equations to be solved to the lowest order possible. This can be done by taking full advantage of the symmetry in some configurations of the boundary conditions. The equations (11) of the system are of such form that they group naturally into combinations having the sums and differences of the voltages as variables. As shown in the Appendix, the set of six equations is now broken into two independent sets of lower order which will yield the same natural frequencies as the original set and also the same wave shapes, if these are symmetrical with respect to the mid-points of the windings. The set of equations obtained by addition yields the symmetrical harmonics for which

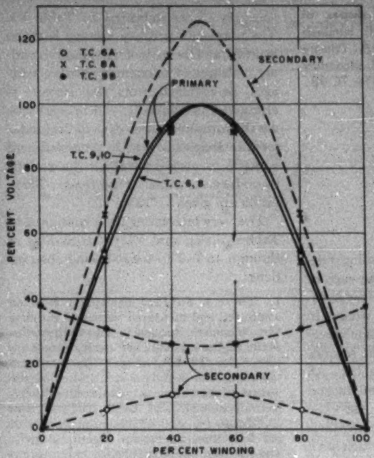

Fig. 9 (left). Wave shapes of first harmonic. All terminals grounded for TC 6A and 8A. Primary terminals grounded, secondary terminals isolated for TC 9B

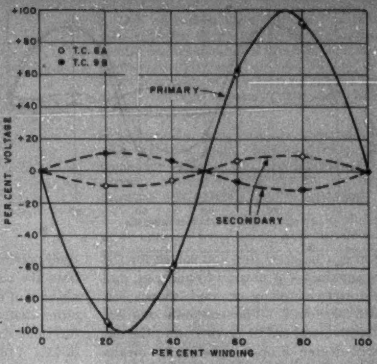
Fig. 11 (right). Wave shapes of second harmonic. All terminals grounded for TC 6A. Primary terminals grounded, secondary terminals isolated for TC 9B



$V_{pa}=V_{pc}$ and $V_{sa}=V_{sc}$ (2)

The set obtained by subtraction yields the antisymmetrical harmonics for which

$V_{pa}=-V_{pc}$ and $V_{sa}=-V_{sc}$ (3)

The calculation of the natural frequencies and wave shapes is greatly simplified by this artifice, and Table III shows the cases when this is possible and the manner into which the equations are divided. The unequal distribution of equations into the two sets (symmetrical and antisymmetrical) is due to the fact that an even number of elements has been used to represent the windings. If an odd number of elements is used the two resulting sets will have the same number of equations.

The method described here for a 2-element representation is easily extended to the 5-element representation to be used for the computations. There are now 13 nodes, 38 elements and 1 separate part, so that the number of independent node pairs is 12. A total of 15 different self- and mutual inductances must be considered, the 2 self-inductances of each element of the primary and secondary, 4 mutual inductances between primary elements and 4 between secondary elements, and finally the 5 mutual inductances between primary and secondary elements. The number of equations, to be solved for the various terminal conditions, is given in Table III. The number of natural frequencies is equal to the order of the determinant, and they can be found by two different methods. The roots of the determinant can be determined by well-known numerical methods, or else a cut-and-try procedure can be used. In the latter case, several frequencies are assumed and the corresponding values of the determinant are calculated: then the frequencies are varied until the values of the determinant become zero.

Determination of the Wave Shapes by Equivalent Circuit

In addition to the natural frequencies of the first three harmonics, it was desired to calculate the wave shapes (or standing waves, or natural modes, or eigenfunctions) corresponding to these oscillations in order to gain a better understanding of the physical phenomena. Lanczos' method,[9,10] which yields both the eigenvalues and eigenvectors, corresponding to the natural frequencies and wave shapes respectively, was used for this purpose. It was first necessary to reduce the circuit equations to a form in which only the terms on the main diagonal contain a constant minus the square of the angular frequency, while all other terms are constant. This form is obtained by multiplying the equations through by the negative of the inverse of the terms in $\lambda=\omega^2$, which are the capacitance terms. The result is an unsymmetrical matrix of the form

$$\|(A-1\lambda)y=0\| \qquad (4)$$

The characteristic equation of this sys-

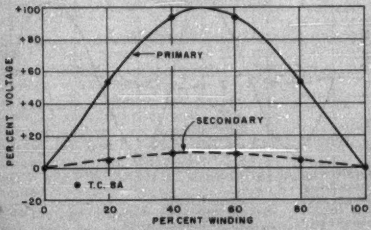


Fig. 10 (left). Wave shape of second harmonic, TC 8A. All terminals grounded

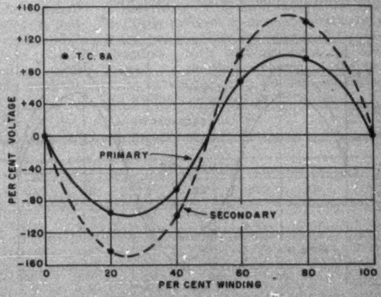

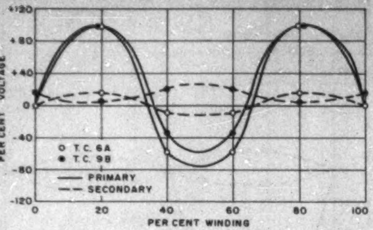

Fig. 13. Wave shapes of third harmonic; all terminals grounded for TC 6A. Primary terminals grounded, secondary terminals isolated for TC 9B

tem can be generated and solved for the eigenvalues λ or natural frequencies, and the eigenvectors y or wave shapes can also be found. The computations are iterative and can be carried on to the desired degree of approximation by means of digital computers. In the calculation of the wave shapes, relative voltage values are obtained only for the five nodal points of each winding. While it is convenient to connect these points with continuous curves for visualization purposes, it must be realized that these curves are necessarily arbitrary.

Example: Natural Frequencies of Coupled Windings in Air or on Iron Core

The equivalent circuit method was used to compute the first three or four natural frequencies of various combinations of two coupled windings in air or on an iron core. The primary winding, 23 inches in diameter and 48 inches long, has 1,800 turns and has been described previously.[1] Various secondary windings, 25 inches in diameter and 48 inches long, were located concentrically to the primary.

Two grounded concentric electrostatic shields represented the core and tank ground planes; see Fig. 3. The different winding combinations are designated as test conditions (TC). Each TC is referred to by a number and by a letter. The numbers from 6 to 10 (1 to 5 were used previously[1,3] for single windings) denote the turn ratio and the presence or absence of the iron core; the letter A denotes that both windings are wound in the same direction; B in opposite directions. A brief description of the secondary windings is given in Table IV. All the capacitances, and the self- and mutual inductances were computed for the various test conditions, using equivalent air-core coils[1] for TC 9 and 10, which have an iron core.

Since almost all high-voltage power systems in the country operate with grounded neutral, all computations were done for this case which corresponds to both primary terminals grounded. Various secondary conditions were investigated: 1. both terminals isolated; 2. both grounded; 3. terminals short-circuited but isolated from ground; 4. one terminal grounded, one isolated. The natural frequencies and their ratios, computed with the 5-element representation as well as the measured frequencies and ratios, are tabulated in Table V. This table includes also a few fundamental frequencies computed with the 2-element representation. To have a complete picture of the effect of the secondary, the measured frequencies are included with secondary absent for air core (corresponding to TC 6,7, and 8) and for iron core (corresponding to TC 9 and 10). The computed wave shapes are shown on Figs. 9 through 15, as indicated in Table VI. The maximum primary voltage is taken as unity, and the ratio of maximum secondary voltages to maximum primary voltages, as obtained from the curves, is also given in Table VI. Of interest also are the measured ratios[1] f_g/f_i of the fundamental frequencies with grounded and isolated primary neutral for the various secondary terminal conditions. These ratios are given in Table VII.

The very interesting data contained in Tables V, VI, and VII and in Figs. 9 through 15 lead to the following observations:

1. There is excellent agreement between computed and measured values of the first three harmonic frequencies and of the ratios of the higher harmonics to the fundamental, except for TC 9B. For TC 6, 7, and 8 (air-core) the standard deviations of the measured and computed values of the fundamental, second, and third harmonic are 10.4%, 10.1% and 16.9% respectively, of the first three harmonics together 12.8%. The standard deviation of the computed and measured frequency ratios is 9.7%. The agreement of the frequency ratios is more significant than the agreement of the frequency values, since the former are less affected by possible errors in the calculation of the coil capacitances. In accordance with theoretical considerations, the computed frequencies are less than the measured frequencies and the difference increases with the harmonic order.[1]

2. There is good agreement between computed and measured wave shapes for TC 9B, for which the first and second harmonic were measured. For the second harmonic, computed relative voltages at 20 and 40% winding from the neutral end were 100 and 69% for the primary, 12 and 8% for the secondary. Corresponding measured values were 100 and 68.8% for the primary, 11.8 and 8.1% for the secondary.

3. In considering the effect of the secondary winding the absolute values and the ratios of the natural frequencies should be discussed separately. Presence of the secondary reduces the natural frequencies with respect to the values with secondary absent. This effect is felt more and more

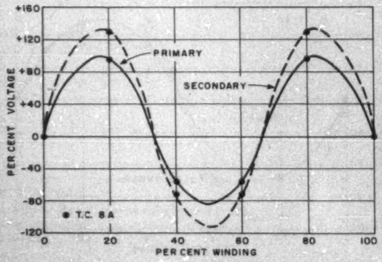

Fig. 14 (left). Wave shape of fourth harmonic, TC 8A. All terminals grounded

Fig. 15 (right). Wave shapes of fourth harmonic. All terminals grounded for TC 6A. Primary terminals grounded, secondary terminals isolated for TC 9B

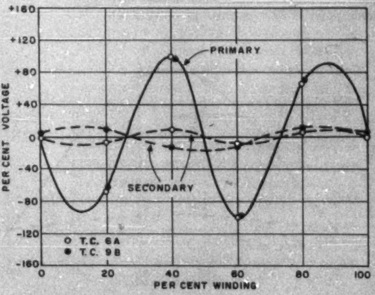

Table VI. Ratios of Maximum Secondary and Primary Voltages

Both Primary Terminals Grounded

TC	Secondary Terminals	n	Figure	Ratio Calculated	Ratio Measured
6A, turn ratio 1/9	Both grounded	1	9	1:9	
		2	11	1:10	
		3	13	1:7	
		4	15	1:10	
8A, turn ratio 1/1	Both grounded	1	9	5:4	
		2	10	1:11	
		3	12	3:2	
		4	14	4:3	
9B, turn ratio 1/8.57	Both isolated	1	9	1:2.67	1:2.6
		2	11	1:8.57	1:7.6
		3	13	1:3.5	
		4	15	1:6.7	

as the turn ratio approaches unity. It increases when the secondary terminal conditions change as follows: 1. both isolated; 2. short-circuited and isolated; 3. both grounded; 4. one grounded, one isolated. The effect of the secondary is also more important when the secondary is wound in the opposite direction to the primary than when it is wound in the same direction. For instance, the novel and interesting fact is revealed that the fundamental frequency for TC 8B is half the value for TC 8A, when both secondary terminals are grounded.

4. The ratios of the natural frequencies show less variation than the absolute values. For instance, the ratio of the second harmonic to the fundamental is the same whether the secondary is absent or present with both terminals grounded, despite variations of the order of 2.5 to 1 in the frequency values. This is because the sum of the primary ampere turns is zero for these modes of oscillation. The ratio of the second to the first harmonic is reduced by the presence of the secondary with isolated terminals, and this effect increases as the turn ratio approaches unity. For unity turn ratio the value of the second harmonic is only slightly greater than the value of the first harmonic.

5. If we look at the voltage distributions for TC 8A with both secondary terminals grounded (Figs. 9 and 10) it is seen that both first and second harmonics have the same wave shapes, and correspond approximately to half a sine wave encompassing each winding. However, the secondary amplitude is 5/4 of the primary amplitude for the first harmonic, but only 1/11 for the second. The third-harmonic frequency is a little larger than the second, but its wave shape, Fig. 12, shows that approximately two half sine waves encompass each winding.

6. For taansmission lines the harmonic order is equal to the number of half sine waves "standing" on the winding. This concept is incorrect for single windings with mutual inductance, but may be still used for visualization purposes. For two coupled windings the harmonic order is simply the order in which the natural frequencies appear and cannot be correlated with the number of standing sine waves.

7. The set of symmetrical equations is the same for both secondary terminals isolated or short-circuited and isolated. Also the set of antisymmetrical equations is the same for both terminals grounded or short-circuited and isolated. Thus the natural frequencies for the case of the secondary short-circuited and isolated are obtained from the values computed for the other two conditions.

8. The ratio f_g/f_i of the fundamental frequencies with grounded and isolated neutral is in agreement with the conclusions obtained in the preceding sections of this paper. This ratio is about the same (about 2.4 for air core, 3.4 for iron core) for secondary absent or isolated at both ends, with the exception of TC 8A (unity turn ratio). This ratio becomes considerably less (1.01 to 1.37) when the secondary is short-circuited, and it makes little difference whether the connected terminals are grounded or isolated. When one secondary terminal is isolated and one grounded, this ratio varies between 0.56 and 2.69 and thus in some cases is less than unity. This ratio also depends upon which terminal is grounded, either the terminal adjacent to the primary line end or to the primary neutral end. It is difficult to obtain a physical picture of these extensive variations.

Conclusions

The following conclusions can be drawn from the theoretical and experimental investigation of the oscillations of two coupled windings presented.

1. A method is presented for the determination of the fundamental frequencies and wave shapes of a primary winding with short-circuited secondary. This method is applicable to windings in air and iron core, if the turn ratio is considerably different from unity.

2. An equivalent circuit method is presented for the determination of the fundamental oscillation and of several successive harmonics, valid for two windings in air or on iron core, of any turn ratio, and for many different primary and secondary terminal conditions.

3. When the turn ratio is considerably different from unity, short-circuiting the secondary affects the frequencies with primary neutral isolated, but not the frequencies with primary neutral grounded.

4. In power transformers the ratio of the first natural frequencies with grounded and isolated neutral usually varies between 5 and 12, if the secondary is absent or open-circuited. If the secondary is short-circuited this ratio depends mainly upon the gap between primary and secondary, and usually varies between 1.1 to 1.6, as verified by measurements.

5. The values of the frequencies of two coupled windings with primary neutral isolated decrease gradually as the secondary terminal conditions change as follows: both terminals isolated; short-circuited and isolated; both grounded; one grounded and one isolated.

6. Measured and computed values of the first three harmonics of two coupled windings in air, with turn ratios varying from 1-to-1 to 1-to-9 and for various secondary terminal conditions, were in excellent agreement. The standard deviation of 33 pairs of computed and measured values was 12.8%, of 22 ratios of the second and third harmonic to the fundamental, 9.7%. Satisfactory agreement was obtained for frequencies and wave shapes of two windings with iron core.

7. As the turn ratio approaches unity, the effect of the secondary is more pronounced when the two windings are wound in opposite directions than when they are wound in the same direction.

8. The computation of impulse voltages in a power transformer may be done with good approximation as heretofore, considering only the impulsed winding, provided that the neutral of the impulsed winding is grounded and the turn ratio differs considerably from unity; for instance, is greater than 4 to 1. These conditions hold for most, but not all, practical cases.

9. If the neutral of the impulsed winding is isolated, or if the turn ratio is not substantially different from unity (particularly if the two windings are wound in opposite directions) both windings must be considered for the determination of the impulse voltages in either winding, employing the methods advanced in this paper.

Appendix. Two-Element Representation

The voltage drops across the inductances in the circuit of Fig. 8 can be expressed in terms of the winding currents since all inductance elements are assumed to be coupled magnetically.

$$\begin{Vmatrix} V_{pba} \\ V_{pcb} \\ V_{sba} \\ V_{scb} \end{Vmatrix} = \begin{Vmatrix} V_{pa}-V_{pb} \\ V_{pb}-V_{pc} \\ V_{sa}-V_{sb} \\ V_{sb}-V_{sc} \end{Vmatrix} = j\omega \begin{Vmatrix} L_{pp} & M_{p1} & M_{ps1} & M_{ps2} \\ M_{p1} & L_{pp} & M_{ps2} & M_{ps1} \\ M_{ps1} & M_{ps2} & L_{ss} & M_{s1} \\ M_{ps2} & M_{ps1} & M_{s1} & M_{ss} \end{Vmatrix} \times \begin{Vmatrix} I_{p1} \\ I_{p2} \\ I_{s1} \\ I_{s2} \end{Vmatrix} \tag{5}$$

These equations can be inverted to obtain the currents in term of the voltages

$$\begin{Vmatrix} I_{p1} \\ I_{p2} \\ I_{s1} \\ I_{s2} \end{Vmatrix} = \frac{1}{j\omega} \begin{Vmatrix} \Gamma_{pp} & \Gamma_{p1} & \Gamma_{ps1} & \Gamma_{ps2} \\ \Gamma_{p1} & \Gamma_{pp} & \Gamma_{ps2} & \Gamma_{ps1} \\ \Gamma_{ps1} & \Gamma_{ps2} & \Gamma_{ss} & \Gamma_{s1} \\ \Gamma_{ps2} & \Gamma_{ps1} & \Gamma_{s1} & \Gamma_{ss} \end{Vmatrix} \times \begin{Vmatrix} V_{pba} \\ V_{pcb} \\ V_{sba} \\ V_{scb} \end{Vmatrix} \tag{6}$$

To write the nodal equations, the total current flowing away from each node, and associated with an inductive element, must be found in terms of the node voltages

$$\begin{Vmatrix} I_{pal} \\ I_{pbl} \\ I_{pcl} \\ I_{sal} \\ I_{sbl} \\ I_{scl} \end{Vmatrix} = \begin{Vmatrix} I_{p1} \\ I_{p2}-I_{p1} \\ -I_{p2} \\ I_{s1} \\ I_{s2}-I_{s1} \\ -I_{s2} \end{Vmatrix} = \frac{1}{j\omega} \begin{Vmatrix} \Gamma_{pp} & \Gamma_{p1}-\Gamma_{pp} & -\Gamma_{p1} & \Gamma_{ps1} & \Gamma_{ps2}-\Gamma_{ps1} & -\Gamma_{ps2} \\ \Gamma_{p1}-\Gamma_{pp} & 2(\Gamma_{pp}-\Gamma_{p1}) & \Gamma_{p1}-\Gamma_{pp} & \Gamma_{ps2}-\Gamma_{ps1} & 2(\Gamma_{ps1}-\Gamma_{ps2}) & \Gamma_{ps2}-\Gamma_{ps1} \\ -\Gamma_{p1} & \Gamma_{p1}-\Gamma_{pp} & \Gamma_{pp} & -\Gamma_{ps2} & \Gamma_{ps2}-\Gamma_{ps1} & \Gamma_{ps1} \\ \Gamma_{ps1} & \Gamma_{ps2}-\Gamma_{ps1} & -\Gamma_{ps2} & \Gamma_{ss} & \Gamma_{s1}-\Gamma_{ss} & -\Gamma_{s1} \\ \Gamma_{ps2}-\Gamma_{ps1} & 2(\Gamma_{ps1}-\Gamma_{ps2}) & \Gamma_{ps2}-\Gamma_{ps1} & \Gamma_{s1}-\Gamma_{ss} & 2(\Gamma_{ss}-\Gamma_{s1}) & \Gamma_{s1}-\Gamma_{ss} \\ -\Gamma_{ps2} & \Gamma_{ps2}-\Gamma_{ps1} & \Gamma_{ps1} & -\Gamma_{s1} & \Gamma_{s1}-\Gamma_{ss} & \Gamma_{ss} \end{Vmatrix} \times \begin{Vmatrix} V_{pa} \\ V_{pb} \\ V_{pc} \\ V_{sa} \\ V_{sb} \\ V_{sc} \end{Vmatrix} \tag{7}$$

The capacitive currents associated with the various nodes are also (by inspection from Fig. 8)

$$\begin{aligned}
I_{pac} &= I_{pp1}+I_{pag}+I_{ps1} = j\omega\left(\frac{C_{pg}+C_{ps}}{2}+C_{pp}\right)V_{pa}-j\omega C_{pp}V_{pb}-j\omega\frac{C_{ps}}{2}V_{sa} \\
I_{pbc} &= I_{pp2}-I_{pp1}+I_{pbg}+I_{ps2} = j\omega(C_{pg}+C_{ps}+2C_{pp})V_{pb}-j\omega C_{pp}V_{pa}-j\omega C_{pp}V_{pc}-j\omega C_{ps}V_{sb} \\
I_{pcc} &= -I_{pp2}+I_{pcg}+I_{ps3} = j\omega\left(\frac{C_{pg}+C_{ps}}{2}+C_{pp}\right)V_{pc}-j\omega C_{pp}V_{pb}-j\omega\frac{C_{ps}}{2}V_{sc} \\
I_{sac} &= I_{ss1}+I_{sag}-I_{ps1} = j\omega\left(\frac{C_{sg}+C_{ps}}{2}+C_{ss}\right)V_{sa}-j\omega C_{ss}V_{sb}-j\omega\frac{C_{ps}}{2}V_{pa} \\
I_{sbc} &= I_{ss2}-I_{ss1}-I_{ps2}+I_{sbg} = j\omega(C_{sg}+C_{ps}+2C_{ss})V_{sb}-j\omega C_{ss}V_{sa}-j\omega C_{ss}V_{sc}-j\omega C_{ps}V_{pb} \\
I_{scc} &= -I_{ss2}+I_{scg}-I_{ps3} = j\omega\left(\frac{C_{sg}+C_{ps}}{2}+C_{ss}\right)V_{sc}-j\omega C_{ss}V_{sb}-j\omega\frac{C_{ps}}{2}V_{pc}
\end{aligned} \tag{8}$$

The nodal equations are formed by simply stating that the sum of the currents flowing away from any node is zero

$$I_{pal}+I_{pac}=0 \qquad I_{pbl}+I_{pbc}=0 \qquad I_{pcl}+I_{pcc}=0 \qquad I_{sal}+I_{sac}=0 \qquad I_{sbl}+I_{sbc}=0 \qquad I_{scl}+I_{scc}=0 \tag{9}$$

Since each inductive term contains a factor $1/j\omega$, the equations can be simplified by multiplying both members by $j\omega$. All capacitive terms will have a factor $\lambda=\omega^2$. If the following abbreviations are used

$$\begin{aligned}
C_{p1} &= \frac{C_{pg}+C_{ps}}{2}+C_{pp}; \quad C_{p2}=C_{pg}+C_{ps}+2C_{pp} \\
C_{s1} &= \frac{C_{sg}+C_{ps}}{2}+C_{ss}; \quad C_{s2}=C_{sg}+C_{ps}+2C_{ss}
\end{aligned} \tag{10}$$

then there is the following system of equations

$$\begin{Vmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{Vmatrix} = \begin{Vmatrix} \Gamma_{pp}-C_{p1}\lambda & \begin{matrix}\Gamma_{p1}-\Gamma_{pp} \\ +C_{pp}\lambda\end{matrix} & -\Gamma_{p1} & \Gamma_{ps1}+\frac{C_{ps}}{2}\lambda & \Gamma_{ps2}-\Gamma_{ps1} & -\Gamma_{ps2} \\ \begin{matrix}\Gamma_{p1}-\Gamma_{pp} \\ +C_{pp}\lambda\end{matrix} & \begin{matrix}2(\Gamma_{pp}-\Gamma_{p1}) \\ -C_{p2}\lambda\end{matrix} & \begin{matrix}\Gamma_{p1}-\Gamma_{pp} \\ +C_{pp}\lambda\end{matrix} & \Gamma_{ps2}-\Gamma_{ps1} & \begin{matrix}2(\Gamma_{ps1}-\Gamma_{ps2}) \\ +C_{ps}\lambda\end{matrix} & \Gamma_{ps2}-\Gamma_{ps1} \\ -\Gamma_{p1} & \begin{matrix}\Gamma_{p1}-\Gamma_{pp} \\ +C_{pp}\lambda\end{matrix} & \Gamma_{pp}-C_{p1}\lambda & -\Gamma_{ps2} & \Gamma_{ps2}-\Gamma_{ps1} & \Gamma_{ps1}+\frac{C_{ps}}{2}\lambda \\ \Gamma_{ps1}+\frac{C_{ps}}{2}\lambda & \Gamma_{ps2}-\Gamma_{ps1} & -\Gamma_{ps2} & \Gamma_{ss}-C_{s1}\lambda & \begin{matrix}\Gamma_{s1}-\Gamma_{ss} \\ +C_{ss}\lambda\end{matrix} & -\Gamma_{s1} \\ \Gamma_{ps2}-\Gamma_{ps1} & \begin{matrix}2(\Gamma_{ps1}-\Gamma_{ps2}) \\ +C_{ps}\lambda\end{matrix} & \Gamma_{ps2}-\Gamma_{ps1} & \begin{matrix}\Gamma_{s1}-\Gamma_{ss} \\ +C_{ss}\lambda\end{matrix} & \begin{matrix}2(\Gamma_{ss}-\Gamma_{s1}) \\ -C_{s2}\lambda\end{matrix} & \begin{matrix}\Gamma_{s1}-\Gamma_{ss} \\ +C_{ss}\lambda\end{matrix} \\ -\Gamma_{ps2} & \Gamma_{ps2}-\Gamma_{ps1} & \Gamma_{ps1}+\frac{C_{ps}}{2}\lambda & -\Gamma_{s1} & \begin{matrix}\Gamma_{s1}-\Gamma_{ss} \\ +C_{ss}\lambda\end{matrix} & \Gamma_{ss}-C_{s1}\lambda \end{Vmatrix} \times \begin{Vmatrix} V_{pa} \\ V_{pb} \\ V_{pc} \\ V_{sa} \\ V_{sb} \\ V_{sc} \end{Vmatrix} \tag{11}$$

Two new sets of equations can be formed from these by adding or subtracting equations in *pa* and *pc*, *sa*, and *sc* and by multiplying the equations in *pb* and *sb* by two in order to retain symmetry

$$\left\| \begin{array}{c} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{array} \right\| = \left\| \begin{array}{cccccc} \Gamma_{pp}-\Gamma_{p1}-C_{p1}\lambda & 2(\Gamma_{p1}-\Gamma_{pp})+2C_{pp}\lambda & \Gamma_{ps1}-\Gamma_{ps2}+\frac{C_{ps}}{2}\lambda & 2(\Gamma_{ps2}-\Gamma_{ps1}) & & \\ 2(\Gamma_{p1}-\Gamma_{pp})+2C_{pp}\lambda & 4(\Gamma_{pp}-\Gamma_{p1})-2C_{p2}\lambda & 2(\Gamma_{ps2}-\Gamma_{ps1}) & 4(\Gamma_{ps1}-\Gamma_{ps2})+2C_{ps}\lambda & & \\ \Gamma_{ps1}-\Gamma_{ps2}+\frac{C_{ps}}{2}\lambda & 2(\Gamma_{ps2}-\Gamma_{ps1}) & \Gamma_{ss}-\Gamma_{s1}-C_{s1}\lambda & 2(\Gamma_{s1}-\Gamma_{ss})+2C_{ss}\lambda & & \\ 2(\Gamma_{ps2}-\Gamma_{ps1}) & 4(\Gamma_{ps1}-\Gamma_{ps2})+2C_{ps}\lambda & 2(\Gamma_{s1}-\Gamma_{ss})+2C_{ss}\lambda & 4(\Gamma_{ss}-\Gamma_{s1})-2C_{s2}\lambda & & \\ & & & & \Gamma_{pp}+\Gamma_{p1}-C_{p1}\lambda & \Gamma_{ps1}+\Gamma_{ps2}+\frac{C_{ps}}{2}\lambda \\ & & & & \Gamma_{ps1}+\Gamma_{ps2}+\frac{C_{ps}}{2}\lambda & \Gamma_{ss}+\Gamma_{s1}-C_{s1}\lambda \end{array} \right\| \times \left\| \begin{array}{c} V_{pa}+V_{pc} \\ V_{pb} \\ V_{sa}+V_{sc} \\ V_{sb} \\ V_{pa}-V_{pc} \\ V_{sa}-V_{sc} \end{array} \right\| \qquad (12)$$

High-Current Testing of Air-Disconnect Switches

BELGRAVE F. GOSTIN
MEMBER AIEE

TENNESSEE VALLEY Authority's rapidly expanding power system and the construction of several large-capacity steam plants have increased the incidence of short-circuit currents to an extent considerably greater than formerly experienced at the Authority or elsewhere. This requires new features in the design and performance of air-disconnect switches which are used to isolate breakers, bus sections, and transmission lines.

The possible magnitude of the fault current caused by a close-in fault to one of the new steam plants has reached a value that is impossible for at least some switch manufacturers to duplicate in their test laboratories. They find it more and more difficult to design a switch on paper that will successfully meet the rigorous requirements.

Since manufacturers could not always supply the information required for application to Tennessee Valley Authority's system, it was decided that a high-current test laboratory should be built and a series of tests undertaken on a number of various makes of disconnect switches in order to obtain the desired data under actual physical conditions.

Scope of Tests

A number of manufacturers were informed of the proposed tests and invited to submit three groups of switches for test purposes as follows:

Group 1, consisting of standard 161-kv switches, rated at 1,200 and 1,600 amperes.

Group 2, consisting of standard 69-kv switches, rated at 600 amperes.

Group 3, consisting of standard 46-kv switches, rated at 600 amperes.

In each group an alternate design switch, if desired, could be submitted.

The proposed tests were planned as follows:

1. In all cases there would be applied to the switch under test a magnetic force equivalent to that which would occur at normal phase spacing.
2. In all cases the test current applied to the switches would be a fully offset wave (maximum transient).
3. All 161-kv switches would be subjected to an initial test current equivalent to a short-circuit fault on a 10,000-mva system.
4. A temperature test would then be made on the switch to determine the extent of damage and the adequacy of design.
5. The switch would then be retested at a value of current equivalent to a short-circuit fault on a 15,000-mva system or it might be tested to destruction in order to determine its ultimate capacity.
6. All 69-kv and 46-kv switches would be tested at values of current recommended by National Electrical Manufacturers Association standards.

Since it was necessary to build the complete high-current laboratory from existing or readily obtainable material, it seemed advisable first to make such laboratory tests as would be required to determine the configuration of a single-

Paper 55-13, recommended by the AIEE Switchgear Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted September 20, 1954; made available for printing October 29, 1954.

phase high-current bus to meet the test specifications.

Preliminary Design

The first requirement to be considered was that of providing for the fully offset test current. This could be obtained only by closing the power supply circuit at zero voltage on the rising half-cycle. Investigation disclosed that this requirement could be met by a spring-operated solenoid-reset air switch of special design. This switch, Fig. 1, was rated 12 kv at 1,200 amperes, it would close in 5 cycles ±10 degrees, and would reset in 20 cycles. The development laboratory then built an electronic timer and sequence operator which would close this switch at the proper instant and provide for reclosing automatically any desired number of times.

The next consideration was to design a bus structure which would act as a current limiter and at the same time provide the required magnetic forces. The dimensions of this bus structure were worked out from laboratory tests on a scale model operated at greatly reduced current. It was determined that this structure should consist of three parallel busses arranged so that the center bus would be fixed and the two outside busses could be varied in spacing from a 1-foot minimum to a 5-foot maximum. Also, there would be provided a short-circuiting bar which could be placed anywhere between 33 feet and 51 feet from the transformer end of the bus.

A 12-foot test section, Fig. 2, was provided in the center bus, within the 33-foot minimum length, in which would be installed the disconnect switches under test. By varying the length of bus and the spacing, the loop impedance could be set to limit the current at any desired value. Also, by setting the two outside busses at different distances from the center bus, any desired resultant force could be applied on the center bus and hence to the disconnect switch under test; see Figs. 3 and 4.

There were available two furnace transformers each rated 2,775 kva at 12 kv to 190-volt 17,000-ampere continuous duty. These transformers could be connected in series on the low-voltage side and, on a momentary basis, would supply a test current of 150,000-amperes rms into the bus structure. It remained then to clear the fault, once it had been established by the high-speed air switch. This was ac-

complished by the use of a 15-kv 600-ampere oil circuit breaker which had a momentary rating of 10,000 amperes.

Finally, it was necessary to provide suitable instrumentation to accomplish two things. First, a positive indication was needed of the point on the 60-cycle voltage wave at which the high-speed air switch closed. This was attained by using a double-channel direct-writing Brush oscillograph with one pen recording the transformer low-side fault current, and the other the transformer low-side voltage.

Second, there had to be accurate measurement of the fault current, the power transformer high and low voltages, and the air switch trip voltage. These measurements were attained with the use of a *PM-13* photographic-type oscillograph connected to a 25,000/5-ampere current transformer for recording the fault current, and to suitable potential transformers for recording the power transformer voltages. Later it was found that valuable additional information could have been obtained from a single-phase watt galvanometer connected to record the total power into the test bus. However, such a galvanometer was not available.

In addition to this instrumentation, two Bell and Howell type-*GSAP* 16-millimeter automatic cameras were mounted in the test bay of the bus structure and were set to photograph the hinge and break ends of the disconnects under test. These cameras operated successfully at their maximum speed of 62 frames per second. However, a higher speed, such as 180 or 240 frames per second, would have been quite an advantage.

Test Bus Structure

The test bus shown schematically in Fig. 5 and described briefly in the foregoing was constructed of $3^1/_2$ -inch aluminum tubing with 3/8 by 4-inch copper used for the short-circuiting bar and the transformer-end jumper.

The force equation for this double loop arrangement, operating single-phase, is

$$F=\frac{43.2(I_cI_1)}{D_1(10^7)}-\frac{43.2(I_cI_2)}{D_2(10^7)}\text{ pounds-per-foot length}\quad(1)$$

where

I = rms current of first half-cycle
D = spacing of bus, inches
F = force developed in pounds-per-foot length of bus

The effective impedance of this double loop, including transformer connections, was measured at reduced current and plotted as shown in Fig. 6. From this family of curves the configuration could be determined to provide a given fault current. Also, the data obtained during impedance measurements gave the division of current through the two outside busses for all symmetrical the nonsymmetrical spacings. Some of these data are reproduced in Table I.

Existing disconnect switches installed on the 161-kv system were designed for a

momentary fault current of 40,000 amperes rms, and assuming a symmetrical 3-phase fault, the magnetic force developed is 55 pounds per foot of length of bus or switch blade. When this value of force, the desired fault current, and the division of current corresponding to an arbitrary selection of bus spacing were substituted back into force equation 1, it was determined that the bus configuration for a 60,000-ampere momentary test would be: length, 33 feet; spacing, 36/27 inches.

For momentary tests on the 46- and 69-kv disconnect switches it was found that by disconnecting one of the outside busses and moving the other to 5-foot spacing (standard for this operating voltage) the available transformers would supply wthout difficulty the desired current into this relatively large loop. Thus, all tests on these two groups of switches were made at standard phase-spacing and National Electrical Manufacturing Association current values. In the final analysis, the exact value of current reached on each test shot was calculated from the *PM-13* oscillograph films according to the AIEE standard No. *22.*[1]

Controls and Instrumentation

The design of all control equipment was based on the premise that the high-speed air switch would be consistent in its operation and would initiate a fully offset test current on every shot. Like all mechanisms, this switch was subject to some variations and required considerable maintenance to keep it in top condition.

It was subject to variation caused by ambient temperature changes and in cold weather (30 to 40 degrees Fahrenheit) would vary as much as 1/2 cycle in its closing times. This variation was finally eliminated by enclosing the switch in a plywood housing and maintaining its temperature at 90 degrees Fahrenheit.

Another source of variation was the erratic operation of the oil shock absorber. On single test shots spaced several minutes apart, the oil shock absorber is satisfactory. However, for quick reclosing shots, spaced 2 or 3 seconds apart, this type of shock absorber is very erratic because of the presence of air bubbles in the oil. An air-damped type of shock absorber would be very much better for this mode of operation.

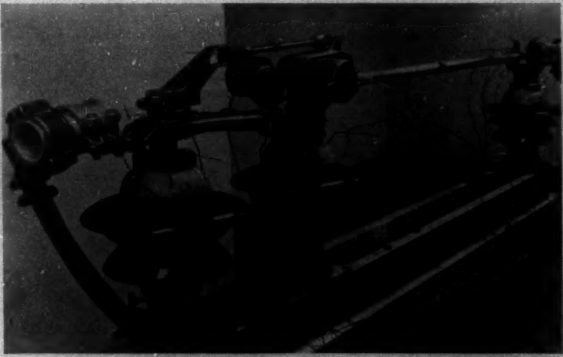

Fig. 8. Temperature test on a 161-kv 1,200-ampere disconnect switch showing placement of thermocouples. Current regulator and test instruments located outside test room

However, for the entire series of tests covering 560 test shots the average transient factor (ratio of rms of first loop to rms of steady state) was 1.48, a very good record indeed.

The control unit for the high-current laboratory, shown schematically in Fig. 7, consists essentially of two parts: 1. a synchronous motor-driven contactor which controls the sequence of operation of the oscillographs, cameras, high-speed air switch, and 12-kv oil circuit breaker, and 2. the thyratron timer circuit, which controls the tripping time of the high-speed air switch.

The motor driven contactor, controlled by a starting push button and a lock-in relay is so arranged that a momentary operation of the push button starts the contactor and seals in its control relay. The contactor continues to run for one revolution and then locks out. Starting with the high-speed air switch open and the oil circuit breaker closed, the following events take place in the order given:

1. Cameras and oscillographs are started.
2. The high-speed air switch is closed.
3. The 12-kv oil circuit breaker is opened.
4. The high-speed air switch is opened.
5. The 12-kv oil circuit breaker is closed.
6. Cameras and oscillographs are stopped.

The contactor automatically locks out at the completion of these events. Should it be desired to make a series of test shots representing the automatic reclosing of a breaker, it is only necessary to hold the starting push button closed for the desired number of test shots.

The elapsed time between reclosings of the test circuit is limited to the operating time of the contactor. In the equipment described, this operating time was 80 cycles. It was based on the over-all operating times of the high-speed air switch and the 12-kv oil circuit breaker. Any decrease in this operating time would have caused considerable difficulty in obtaining the proper sequence of events.

The electronic timer consists essentially of a phase shifter, a peaking transformer, and a grid-controlled thyratron tube. The trip coil of the high-speed air switch is directly in the plate circuit of the thyratron tube. Since the thyratron plate supply is obtained from a station battery, it is necessary to use an auxiliary switch on the high-speed air switch to open the plate circuit upon completion of the tripping operation so that the grid bias may regain control of the thyratron.

The peaking transformer converts the sine wave grid signal voltage to a single sharp pulse for each half-cycle of the sine wave. In stand-by operation the bias voltage is always greater than the positive pulse of signal voltage and thus the thyratron tube is blocked. When the starting push button is depressed, the grid bias voltage is reduced to a value which is less than the positive pulse of signal voltage and thus the thyratron tube fires, closing the trip circuit to the high-speed air switch.

The positive pulse of signal voltage is shifted with respect to the sine wave 12-kv supply by means of the phase shifter, making it possible to adjust the over-all circuit so that the high-speed air switch contacts close just as the 12-kv supply goes through zero. This is the setting which gives maximum transient current into the test bus.

Temperature tests were made only on the 161-kv group of disconnect switches. The switches were operated at rated current, and the temperature was measured at from 15 to 20 points on the current-carrying parts of the switch by means of copper-constantan thermocouples and a portable potentiometer. The test current applied to the disconnect switch was supplied through an induction regulator and a loading transformer having a low-voltage winding rated 5 volts at 2,000 amperes. Fig. 8 shows one of the disconnect switches set up on temperature test. Some of the results of these tests will be discussed in a subsequent article.

Effect of Synchronous-Machine Transient Rotor Saliency on Changes in Terminal Voltage

C. CONCORDIA
FELLOW AIEE

Synopsis: This paper presents the results of calculations made to determine the magnitude of the error in measurements of changes in bus voltages resulting from the assumption of a symmetric-rotor synchronous machine as usually made in transient stability studies on the a-c network analyzer. It is found that in some cases the effect of transient rotor saliency is important. (See the Appendix for explanation of terms.) In such cases the curves of this paper may be used to help estimate the magnitude of the error involved.

IN MOST studies of power system disturbances made on the a-c network analyzer, the transient rotor saliency of the synchronous machines is neglected. The validity of this assumption is well established. However, in some cases it has been desirable to measure the variations in several of the bus voltages during the disturbance. When the bus is electrically near to a synchronous machine (in the limit, when the voltage in question is at the terminals of one of the synchronous machines) the validity of neglecting saliency may be questioned. The paper presents curves of voltage variation at the terminals of a synchronous machine both including and neglecting machine saliency. From these curves, an estimate of the error involved in particular cases may be obtained.

System Considered

The system analyzed consists of a synchronous machine, tied through reactance to an infinite bus. Three initial load conditions on the synchronous machine were considered:

1. Full load, unit terminal voltage, 0.8 power factor (pf).
2. Full load, unit terminal voltage, 1.0 pf.
3. Zero load, unit terminal voltage, zero current.

Paper 55-3, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31-February 4, 1955. Manuscript submitted March 24, 1954; made available for printing October 27, 1954.

C. CONCORDIA is with the General Electric Company, Schenectady, N. Y.

The calculations upon which this paper is based were made by Mrs. M. S. Dyrkacz of the General Electric Company.

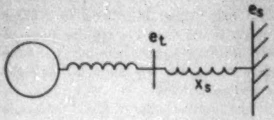

Fig. 1. System diagram

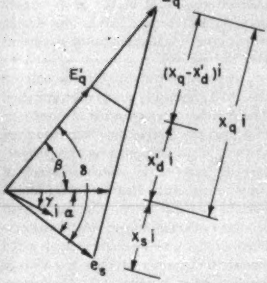

Fig. 2. Voltage phasor diagram

The initial tie-line reactance was taken as 0, 0.2, 0.4, and 0.8 per unit on the machine base. The direct-axis reactance x_d' of the machine is 0.3 per unit. (This will almost always be interpreted as the transient reactance.) The quadrature-axis reactance x_q of the machine was given three values: 0.3 (no saliency, to correspond to the usual assumption made in transient stability studies), 0.6, and 1.2. These three values of x_q should cover the range found in most applications. The value of x_d' is larger than may be found at the terminals of a turbine-generator, but is taken as being possibly the most nearly representative value for a range of cases. A schematic diagram of the system is shown in Fig. 1. In this figure, e_t is the machine terminal voltage and e_s is the equivalent voltage back of the system reactance x_s.

The voltage phasor diagram of this system is shown in Fig. 2. From this diagram the initial values of system voltage e_s and machine field flux E_q' may be determined. Both e_s and E_q' are assumed constant during the subsequent disturbance, and the resulting value of terminal voltage e_t calculated. Two kinds of disturbances are considered:

1. The angle δ of the machine relative to the system is varied, corresponding to a swing of the machine.
2. The system reactance x_s is varied, corresponding to the switching out or in of some line or other part of the system.

Method of Calculation

The initial conditions are calculated from the phasor diagram of Fig. 2 by the relations

$$e_s^2=(e_t-x_si\sin\gamma)^2+(x_si\cos\gamma)^2 \tag{1}$$

$$E_q^2=(e_t+x_qi\sin\gamma)^2+(x_qi\cos\gamma)^2 \tag{2}$$

where γ = initial power factor angle.

$$\alpha=\tan^{-1}\frac{x_si\cos\gamma}{e_t-x_si\sin\gamma} \tag{3}$$

$$\beta=\tan^{-1}\frac{x_qi\cos\gamma}{e_t+x_qi\sin\gamma} \tag{4}$$

$$\delta=\alpha+\beta \tag{5}$$

$$i_d=i\sin(\beta+\gamma) \tag{6}$$

$$E_q'=E_q-i_d(x_q-x_d') \tag{7}$$

The terminal voltage e_t following the disturbance is calculated, with E_q' and e_s as previously determined, from the relations

$$i_d=\frac{E_q'-e_s\cos\delta}{x_d'+x_s} \tag{8}$$

$$i_q=\frac{e_s\sin\delta}{x_q+x_s} \tag{9}$$

$$i^2=i_d^2+i_q^2 \tag{10}$$

$$\epsilon=\tan^{-1}\frac{i_d}{i_q} \tag{11}$$

$$\phi=\delta-\epsilon=\text{angle between } i \text{ and } e_s \tag{12}$$

$$e_t^2=(e_s-x_si\sin\phi)^2+(x_si\cos\phi)^2 \tag{13}$$

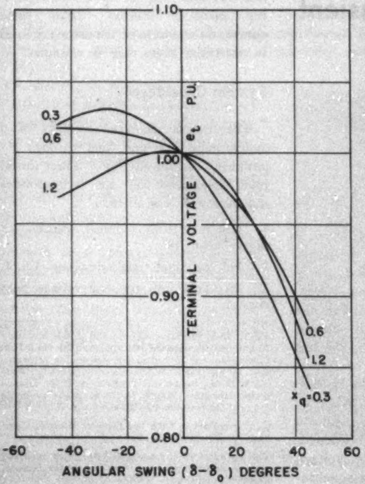
where either x_s or δ is changed from the initial conditions.

Also, the power is

$$e_si\cos\phi \tag{14}$$

Results

The principal results are shown in Figs. 3 through 19.



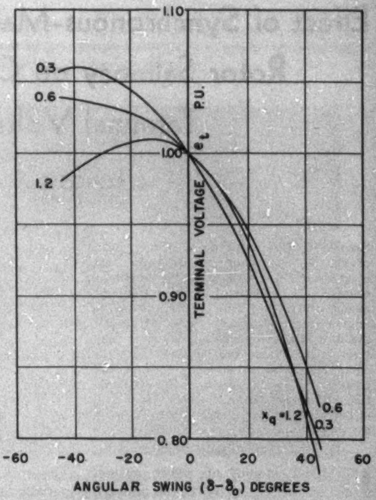


Fig. 3 (left) and Fig. 4 (right). Effect of synchronous-machine transient saliency on variation of terminal voltage with angle

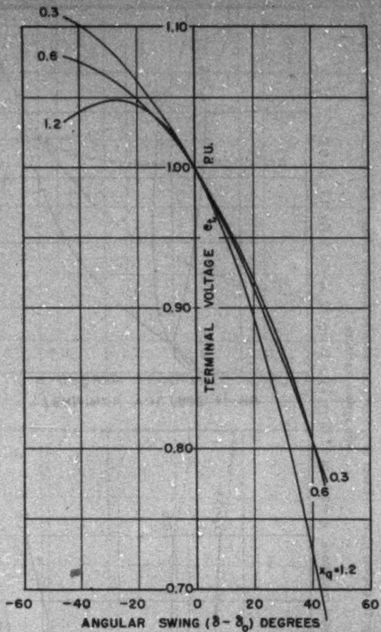
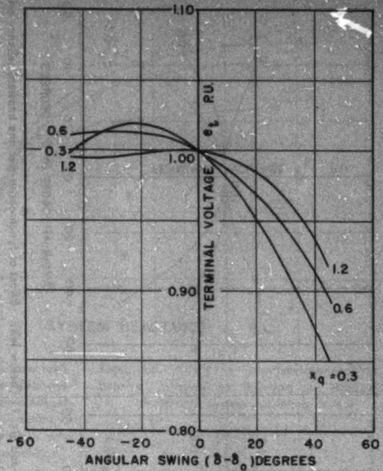
Initial conditions: e_t=1.0; pf=1.0; i=1.0

In Fig. 3, x_s=0.2; for x_q=0.3, δ_0=28.0 degrees (°); for x_q=0.6, δ_0=42.3°; for x_q=1.2, δ_0=61.5°

In Fig. 4, x_s=0.4; for x_q=0.3, δ_0=38.5°; for x_q=0.6, δ_0=52.8°; for x_q=1.2, δ_0=72.0°





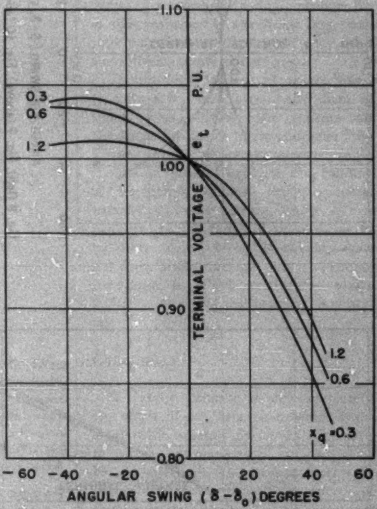


Fig. 5 (above left), Fig. 6 (above right), and Fig. 7 right). Effect of synchronous-machine transient saliency on variation of terminal voltage with angle

Initial conditions for Fig. 5: $e_t=1.0$, pf=1.0, $i=1.0$
In Fig. 5, $x_s=0.8$; for $x_q=0.3$, $\delta_0=55.4°$; for $x_q=0.6$, $\delta_0=69.6°$; for $x_q=1.2$, $\delta_0=88.9°$

Initial conditions for Figs. 6 and 7: $e_t=1.0$; pf=0.8; $i=1.0$
In Fig. 6, $x_s=0.2$; for $x_q=0.3$, $\delta_0=21.8°$; for $x_q=0.6$, $\delta_0=29.7°$; for $x_q=1.2$, $\delta_0=39.5°$
In Fig. 7, $x_s=0.4$; for $x_q=0.3$, $\delta_0=34.3°$; for $x=_q0.6$, $\delta_0=42.3°$; for $x_q=1.2$, $\delta_0=52.0°$

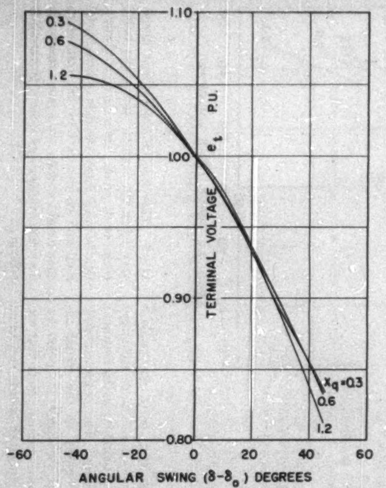
Figs. 3 through 11 show transient terminal voltage e_t as a function of angular swing $\delta-\delta_0$ (from the initial value δ_0) for various degrees of saliency.

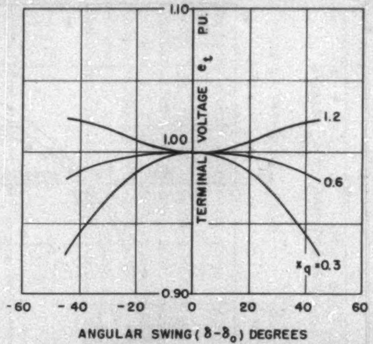
Figs. 3 through 5, for unity terminal pf before the disturbance, indicate that the actual transient change of terminal voltage for a salient-pole machine is somewhat smaller than that obtained neglecting saliency when the system reactance is fairly small ($x_s=0.2$, Fig. 3), but may be slightly greater for positive angular swings when the system reactance is large ($x_s=0.8$, Fig. 5).

Figs. 6 through 8, for 0.8 terminal pf (overexcited) before the disturbance, show that the system behaves qualitatively just the same as for unity pf.

Figs. 9 through 11 for zero initial load and current show, first, that for small angular changes the voltage changes are negligible and, second, that for larger angular changes consideration of rotor saliency actually may cause the voltage to increase rather than decrease. Thus, neglect of saliency may in this case actually cause the indicated voltage change to be of the wrong sign.

Figs. 12 through 19 show the transient terminal voltage e_t as a function of system reactance x_s (with the angle δ fixed), as the system reactance is changed (presumably by switching in the network) to various values. The point on each curve corresponding to the initial reactance (before switching) is circled for convenient identification. Note that the case is now included of system reactance $x_s=0$. This was, of course, not necessary when the angular swing was being considered, since then $e_t=e_s$ always. On the other hand, the case of zero initial load and current is now left out, since then a sudden change of system reactance does not produce any change in terminal voltage.





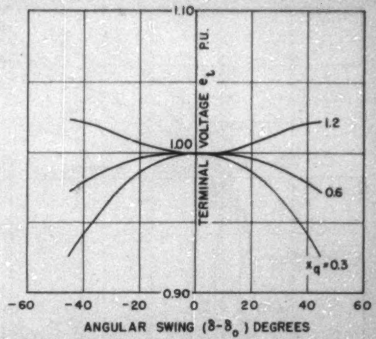


Fig. 8 (left), Fig. 9 (above), Fig. 10 (above right), and Fig. 11 (below left). Effect of synchronous-machine transient saliency on variation of terminal voltage with angle

Initial conditions for Fig. 8: $e_t=1.0$; pf=0.8; i=1.0. Initial conditions for Figs. 9, 10, and 11: $e_t=1.0$; $\delta_0=0$; i=0. Initial conditions for Fig. 8, $x_e=0.8$; for $x_q=0.3$, $\delta_0=62.4°$; for $x_q=0.6$, $\delta_0=70.3°$; for $x_q=1.2$, $\delta_0=80.1°$. In Fig. 9, $x_e=0.2$; in Fig. 10, $x_e=0.4$; in Fig. 11, $x_e=0.8$

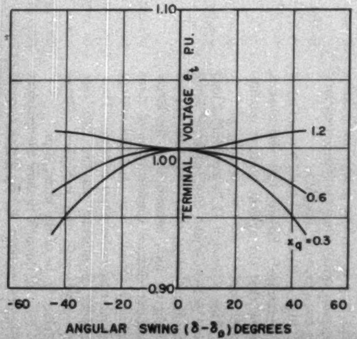

Fig. 12 (below) and Fig. 13 (below right). Effect of synchronous-machine transient saliency on variation of terminal voltage with system reactance

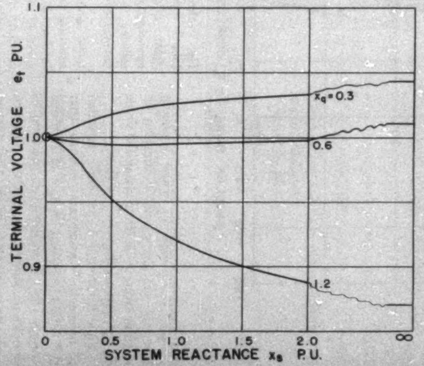
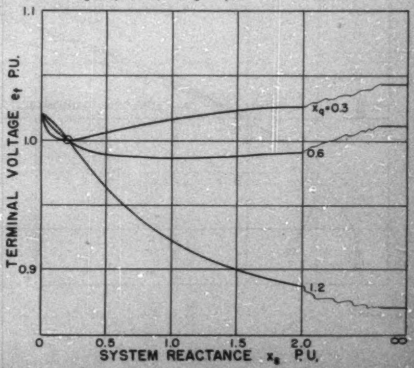
Initial conditions: $e_t=1.0$; pf=1.0; i=1.0. In Fig. 12, $x_e=0$; in Fig. 13, $x_e=0.2$





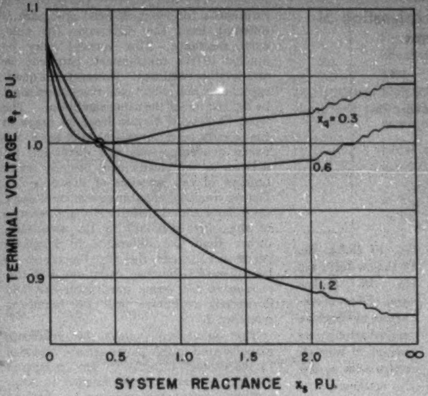


Fig. 14 (above left). Effect of synchronous-machine transient saliency on variation of terminal voltage with system reactance

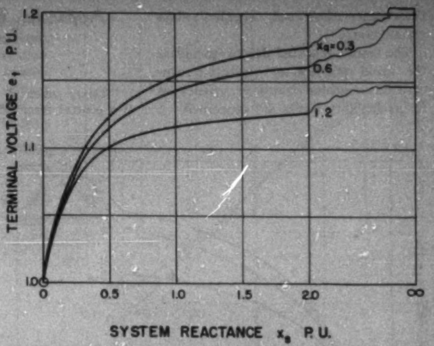
Initial conditions: $e_t=1.0$; pf=1.0; i=1.0



Figs. 16. Effect of synchronous-machine transient saliency on variation of terminal voltage with system reactance; $x_e=0$

Initial conditions: $e_t=1.0$; pf=0.8; I=1.0

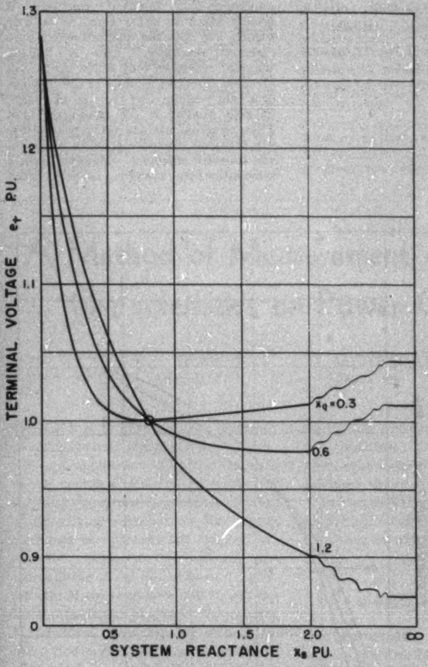


Fig. 15 (left). Effect of synchronous-machine transient saliency on variation of terminal voltage with system reactance; $x_e=0.8$

Initial conditions: $e_t=1.0$; pf=1.0; i=1.0

Figs. 12 through 15, for unity terminal pf initially, show that now the transient voltage change of a salient-pole machine is greater than would be obtained neglecting saliency, and is, moreover, in the opposite direction. There is really little resemblance between the actual change (assuming the machine actually has x_q greater than x_d') and the change calculated neglecting saliency.

Figs. 16 through 19, for 0.8 terminal pf, overexcited, show an opposite effect. Now the transient voltage change including saliency is somewhat less than that calculated neglecting saliency, and the differences are not so great.

Finally Figs. 20 and 21 are included to show a few examples of the effect of synchronous-machine rotor saliency on the transient power angle characteristic. These curves of power versus angle change in general confirm the validity of neglecting saliency in the usual transient-stability swing curve. For instance, in the range of positive increments in angle $[(\delta-\delta_0)>0]$ saliency does not seem important, and this is of course the range in which a machine whose stability is critical will usually be swinging.

Conclusion

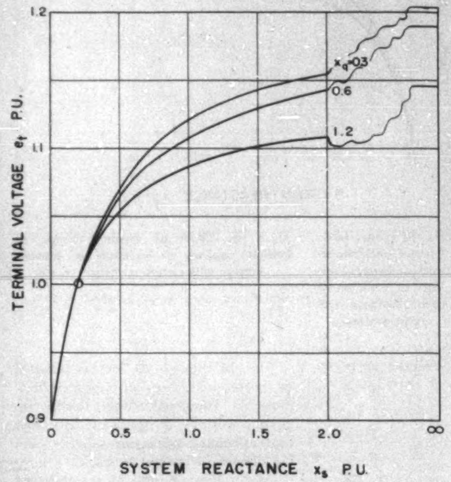
It is not possible to dismiss completely the effect of synchronous-machine transient rotor saliency as far as variations in voltage are concerned. Saliency may be negligible in some cases, but it is suggested that in general the curves of this paper may be used to help determine whether or not saliency is significant. If it is, then it either can be properly taken into account in the study, or these curves may be of assistance in obtaining estimates of correcting factors. The effect of saliency is most pronounced in those cases where sudden changes in system reactance, as viewed from the machine in question, are involved, as compared to those cases where only angular swings are involved.

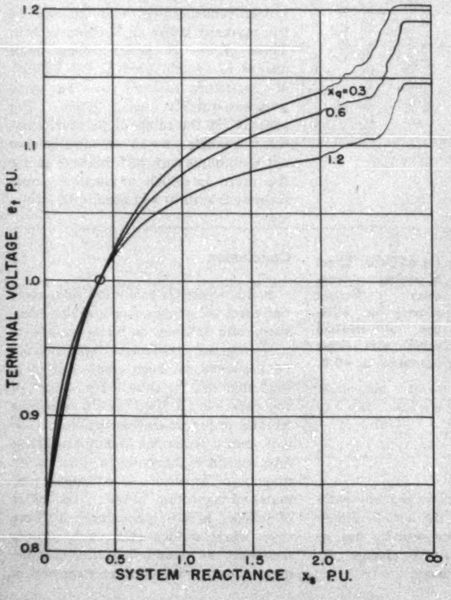
The results reported do not invalidate the usual practice of neglecting synchronous machine transient saliency as far as stability limits are concerned.

Appendix. Explanation of Terms

"Rotary saliency" as used in this paper is a general term meaning that the quadrature-axis (or interpole-axis) reactance is different from the direct-axis (or pole-axis) reactance. This concept may be applied to the subtransient, transient, or steady-state condition. However, the quadrature-axis and direct-axis reactances must be defined under the same conditions. The word "saliency" derives from its usage in the steady state since the difference between quadrature-axis and direct-axis reactance in the steady state usually arises because of the presence of salient poles. During transient or subtransient conditions, the difference in the electrical characteristics of the rotor windings in the two axes, rather than the difference in magnetic permeance, causes the two reactances to be different. Further definition and discussion of the terms quadrature-axis and direct-axis reactance will be found in reference 1.

The numerical values of reactance actually used in this paper are not intended to correspond directly to any particular machine but are merely designed to cover a range. Any actual case can be obtained by interpolation or extrapolation. The quadrature-axis transient reactance is usually taken as either equal to or only slightly less than the quadrature-axis synchronous reactance. This is because transient reactance only differs from synchronous reactance because of the presence of a field winding, and there is, of course, no field winding in the quadrature axis. Thus, no actual machine has its quadrature-axis transient reactance equal to its direct-axis transient reactance. However, such a symmetric-rotor machine is very often





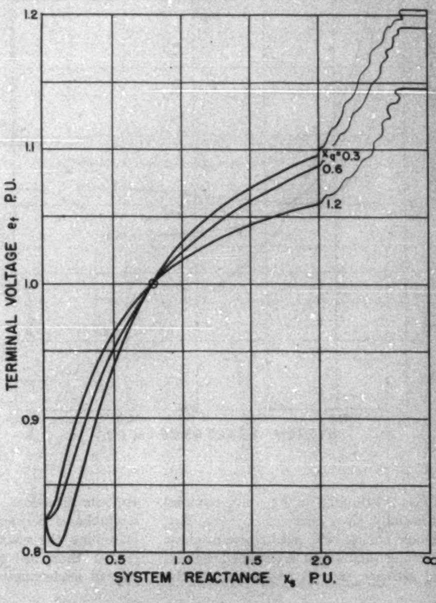


Fig. 17 (left), Fig. 18 (below left), and Fig. 19 (below right). Effect of synchronous-machine transient saliency on variation of terminal voltage with system reactance

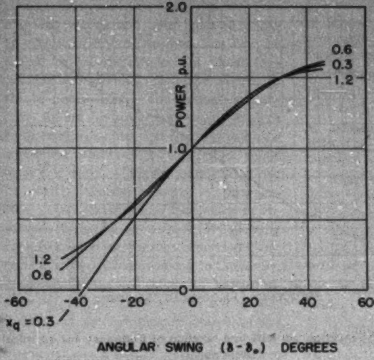
Initial conditions: e_t=1.0, pf=0.8, i=1.0

In Fig. 17, x_s=0.2
In Fig. 18, x_s=0.4
In Fig. 19, x_s=0.8



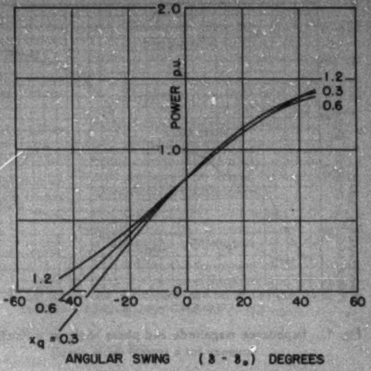


Fig. 20 (left) and Fig. 21 (right). Effect of synchronous - machine transient saliency on variation of power with angle

Initial conditions: $e_t = 1.0$, $i = 1.0$, $x_e = 0.4$
In Fig. 20, pf = 1.0 initially
In Fig. 21, pf = 0.8 initially

assumed for the purpose of simplifying the calculations in engineering studies.

The effect of transient rotor saliency on variations in terminal voltage during disturbances arising from changes of machine angle or of system reactance has been shown in this paper. The effect of transient rotor saliency on changes in terminal voltage arising from the sudden application of shunt loads has already been shown in references 2, 3, and 4, and has been more completely discussed in chapter 9 of reference 1.

A Method of Measurement of Carrier Characteristics on Power Cables

B. J. SPARLIN
MEMBER AIEE

J. D. MOYNIHAN
MEMBER AIEE

THERE is an increasing use of carrier channels over power cables. The design and application of carrier channels require complete electrical information of the cables at carrier frequencies. By use of simplifying assumptions, the parameters can be approximated but not accurately calculated. In general, the power factor of the insulation and the resistance of the conductor and sheath can be approximated at carrier frequencies. If individual conductors are used, it appears that each phase conductor can be considered as a coaxial cable, but this has not yet been completely verified by field tests. The many unknown quantities necessary for accurate calculations of the transmission parameters of the cable make further field tests advisable. The purpose of this paper is to present a test method which has been used and some of the theoretical considerations given to the test procedure. This test method has given values which are consistent with established theory.

The general theory of attenuation and phase shift is based on transmission equations that are well known. These are

$$E_s = E_r \cosh l\sqrt{ZY} + I_r Z_0 \sinh l\sqrt{ZY} \qquad (1)$$

$$I_s = I_r \cosh l\sqrt{ZY} + \frac{E_r}{Z_0} \sinh l\sqrt{ZY} \qquad (2)$$

The characteristic impedance of a transmission line is defined as

$$Z_0 = \sqrt{Z/Y} \qquad (3)$$

where

E_s = sending-end voltage
I_s = sending-end current
E_r = receiving-end voltage
I_r = receiving-end current
$Z = (R + j\omega L)$ per unit length of line
$Y = (G + j\omega C)$ per unit length of line
l = length of line in same units

The significance of the terms Z and Y, as applied for carrier channels in equations 1, 2, and 3, are sometimes overlooked. Z is generally assumed to be $j\omega L$ of the line and Y is assumed to be $j\omega C$ of the line. In carrier applications this assumption cannot be made since R and G are not negligible. As a result, $\sqrt{ZY}$ and $\sqrt{Z/Y}$ are usually complex numbers. Very seldom does $\sqrt{Z/Y}$ take on the purely resistive value as is commonly assumed, even though it sometimes approaches this value. $\sqrt{ZY}$ is defined as the propagation constant γ, which is also defined as $\alpha + j\beta$, where

α = the attenuation constant, nepers per unit length
β = the phase shift, radians per unit length

It is significant to point out that Z_0 in equation 4 can be purely resistive only where Z and Y have the same phase angle

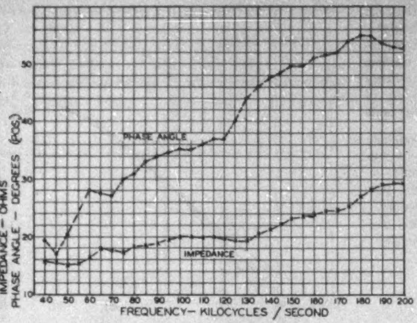

Fig. 1. Impedance magnitude and phase angle as a function of frequency for a typical cable circuit

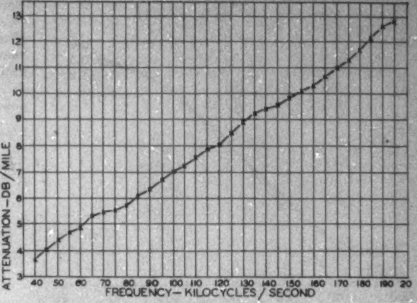

Fig. 2. Attenuation per mile as a function of frequency for a typical cable circuit

$$Z_0 = \sqrt{Z/Y} = \sqrt{(R+j\omega L)/(G+j\omega C)} \qquad (4)$$

It should be noted that equal phase angles are the essential factor, not the fact that R and G are negligible. It is further interesting to note that in the consideration of the propagation constant

$$\gamma = \sqrt{ZY} = \sqrt{(R+j\omega L)(G+j\omega C)} = \alpha + j\beta \qquad (5)$$

If R and G are assumed to be negligible as mentioned in the foregoing, the expression for γ is purely reactive and the attenuation factor becomes zero. Since it is accepted that the attenuation α can not be zero, it must be acknowledged that R and G are not negligible. If R and G are not negligible, then it will only be the exceptional case of $(R + j\omega L)$ and $(G+j\omega C)$ having the same phase angle that will yield a characteristic impedance Z_0 that is purely resistive.

There is at present little known or published information about the characteristics of cables at carrier frequencies. Therefore, the conductance which takes into account the leakage resistance, dielectric absorption losses, and displacement current is a very difficult value to calculate. Also the fact that R is normally small compared with $j\omega L$, and G is normally small compared with $j\omega C$, makes comparatively accurate values essential to arrive at a reasonable value for the phase angle of Z_0 and an attenuation factor. It is with these basic concepts in mind that the methods of measuring Z_0, α, and β are proposed.

Characteristic Impedance

There are several methods for measuring Z_0, the most common of which are the substitution method and the open-circuit–short-circuit method. The substitution method becomes somewhat cumbersome when substituting both an R component and an X component. Measuring the cable impedance and phase angle at the sending end does not give a clear indication of the magnitude of change necessary for the R or X termination at the receiving end to make the two impedances equal. This method therefore becomes a trial-and-error method. Fig. 1 shows impedance and phase angle as a function of frequency.

The open-circuit–short-circuit method is a much more direct method and for this reason it was chosen. From the equation

$$Z \text{ input} = \frac{E_s}{I_s} = \frac{Z_0(Z_r \cosh \gamma l + Z_0 \sinh \gamma l)}{(Z_0 \cosh \gamma l + Z_r \sinh \gamma l)} \qquad (6)$$

it can be shown that

$$Z_0 = \sqrt{Z_{oc} Z_{sc}} \qquad (7)$$

By using an impedance bridge which will measure the impedances Z_{oc} and Z_{sc} including their respective phase angles, it is a simple matter to calculate both the characteristic impedance and the characteristic phase angle. Measuring the sending-end voltage and current for the two conditions is not sufficient unless a reliable means of determining the phase angle is also used. If a line is sufficiently long, the input impedance will almost equal the characteristic impedance regardless of the termination. For instance, if αl is 2.3 nepers or more, the input impedance of a line will be within 2 per cent of the Z_0 even for the extreme terminations of open circuit and short circuit.

Attenuation

To measure the attenuation by measuring either received voltage or current, the line must be terminated in the same impedance as the input impedance, i.e., the characteristic phase angle and magnitude. Fig. 2 shows attenuation as a function of frequency.

The attenuation normally is given in decibels (DB) and is calculated as follows

$$\text{DB} = 10 \log_{10} (P_s/P_r)$$

$$\text{DB} = 10 \log_{10} \frac{E_s^2/(R_s+jX_s)}{E_r^2/(R_r+jX_r)} \qquad (8)$$

If $(R_s + jX_s)$ is equal $(R_r + jX_r)$, then

$$\text{DB} = 20 \log_{10} (E_s/E_r) \qquad (9)$$

It is suggested that a known voltage be applied at the sending end and this voltage be measured across the characteristic impedance at the receiving end with a frequency selective voltmeter. It is significant to point out that errors can be avoided by the use of a frequency selective voltmeter. Oftentimes, ground currents will cause a difference in potential along the sheath of the cable, and the resultant current flow in the cable will give a false reading when read on a broad-band voltmeter. The sending end can usually be monitored with a broad-band voltmeter when the applied voltage is relatively high.

Phase Shift

To measure phase shift in the field is somewhat more difficult than the two previously discussed quantities. It was found that two phases of installed cable could be jumpered at the far end so that the transmitting and receiving terminals of the cable were both at one location. Then the applied voltage and received voltage can both be applied to an oscilloscope.

As the frequency is increased, the

standing waves will pass from in phase (represented by a straight line on the scope) to 180 degrees out of phase (appearing as a straight line perpendicular to the in phase line). The frequency-scanning should be started at a low enough frequency to insure that the first in-phase frequency observed is that of a single standing wave. This frequency then can be plotted against velocity of propagation. As each in-phase frequency is observed, it too can be plotted. By plotting each frequency and recognizing that there can be no sharp discontinuity in the curve, it is possible to tell where, if any, multiples of the fundamental did not appear because of the complex reactance of the circuit.

This method leaves room for error if not executed by an individual familiar with the technique but, with a little experience, this method gives reliable results without elaborate or unusual test equipment.

Test Procedure

The following method has been used several times and has given consistent results. A step-by-step procedure is given for the sake of clarity.

1. Connect drain coils between each of the 3-phase conductors and the cable sheaths at each end of the cable.
2. Open the grounding disconnects on the cable at each end. (Allow sufficient time for cable to discharge before step 2.)
3. Connect an impedance bridge across the drain coil of one cable phase to be measured.
4. Measure impedance of this cable phase with the remote end open- and short-circuited at 5-kc intervals from 40 to 200 kc.
5. Compute the characteristic impedance Z_0 at each of the 5-kc intervals by means of the equation $Z_0=\sqrt{Z_{oc}Z_{sc}}$.
6. If either or both of the other phase conductors are of different construction, measure them as in steps 3 through 5.
7. Disconnect impedance bridge from cable.
8. Connect signal generator and vacuum-tube voltmeter to the phase to be measured. Connect variable *R*, *L*, and *C* and frequency selective voltmeter to the receiving end of this phase.
9. Terminate the cable in its characteristic impedance by adjusting *R*, *L*, and *C* to the characteristic impedance.
10. Transmit a known reference level of signal and measure the received level across the terminating impedance with the frequency selective voltmeter.
11. Steps 9 and 10 are repeated at 5-kc intervals from 40 to 200 kc.
12. Steps 8, 9, 10, and 11 are repeated for any phase conductor that is different from the first one measured.
13. Two phase conductors of the same construction are jumpered at the remote end. Assuming these are phases *B* and *C*, it is now possible to transmit locally on phase *B* and receive the signal locally on phase *C*.
14. Terminate *C* locally with the *R*, *L*, and *C* adjustment for approximate characteristic impedance termination.
15. Steps 9 and 10 are repeated at a few frequencies to ascertain that normal ground currents have not influenced the previous attenuation measurements.
16. Connect the cable input and cable output to the horizontal and vertical inputs of the oscilloscope.
17. Adjust the frequency of the oscillator to give a series of in-phase and 180-degree out-of-phase indications to determine the propagation velocity of the cable.

Conclusion

An attempt has been made to set up a test procedure that is consistent with transmission line theory. Test equipment commonly available has been used, and the results obtained have been consistent within the accuracy of the test equipment. The results are also consistent with transmission line theory and the meager amount of information presently available.

Field Current Sources for Electric Defibrillation

PAUL L. BETZ
MEMBER AIEE

UNDER certain conditions, the heart may lose its rhythmic pumping action and cease to maintain circulation of the blood. This situation is known as ventricular fibrillation and may occur during surgical procedures or as a consequence of electric shock. When ventricular fibrillation occurs in the hospital operating room, a countermeasure is to open the chest and massage the heart to reestablish blood circulation and then to employ a defibrillation procedure that consists of passing a suitable electric current through the heart itself. This is done by applying electrodes to the surface of the heart and passing a 60-cycle alternating current of about 1.5 to 2.0 amperes (amp) through the heart for about 0.5 second (voltage between 120 and 135 volts). Current so applied brings the heart to rest and holds it at rest until the current is interrupted at which time the heart will usually resume its normal rhythmic pumping action provided the elapsed time of fibrillation is not excessive.

When ventricular fibrillation occurs outside of the operating room, conditions do not permit opening the chest to expose the heart for the application of electrodes. Kouwenhoven and Milnor[1] have explored a method of defibrillation that may be applied with the chest intact and under field conditions. The proposed method employs electrodes that are placed on the surface of the body and through which an electric current is passed, the magnitude of which is sufficient to accomplish defibrillation, provided the heart is not cyanotic.

Electric utility companies are especially interested in a defibrillation method which can be applied in the field, since electric shock is an ever-present hazard and is a subject to which continuous attention is given. It is recognized that much will have to be accomplished before defibrillating procedures may be practiced by nonmedical personnel but, to evaluate the possibilities of the method, it is necessary to have a source of electric current suitable for use in the field where commercial power may not be available. During the

Paper 55-87, recommended by the AIEE Safety Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 19, 1954; made available for printing November 18, 1954.

PAUL L. BETZ is with the Consolidated Gas Electric Light and Power Company of Baltimore, Baltimore, Md.

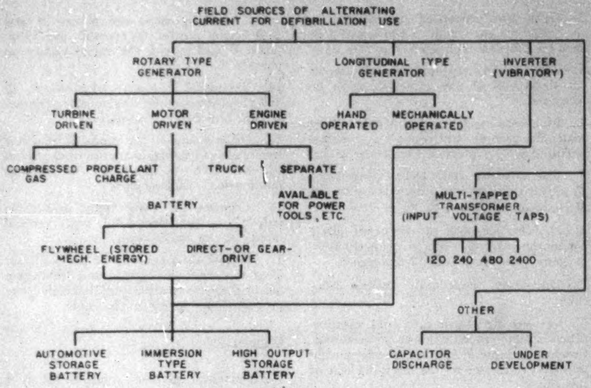

Fig. 1. Current sources for field use

past 2½ years, the author has undertaken to explore the possibilities of obtaining a suitable field power source while Kouwenhoven has concentrated on the development of defibrillation methods using electrodes applied to the surface of the body. The purpose of this paper is to outline briefly the various sources that were investigated and to point to those that appear to meet best the requirements of the field defibrillation method.

Electrical Requirements

The electrical requirements for heart defibrillation can be stated in terms of requirements as determined from animal experiments, since this method has not been applied to human subjects. Experiments were performed using anesthetized dogs[1] and from these the following requirements for the power source were obtained: voltage = 480 volts; current capability = 15 amp; frequency = 60 cycles; and load time = 1 second.

A power source meeting these requirements has been found to give satisfactory results with electrodes placed on opposite sides of the chest. Other experiments using a different electrode position, as described by Kouwenhoven and Milnor,[1] indicate that defibrillation may be accomplished with currents on the order of 4 to 6 amp at the previously mentioned voltage and frequency. The opinion has been expressed that the current necessary for human heart defibrillation will not exceed that used in the more recent experiments, i.e., it will be in the range of 4 to 6 amp. The field current sources that have been investigated are based on delivering 15 amp at the required voltage and frequency and, if the lower current values may be employed, some reduction in the size of equipment may be possible.

In addition to the electrical requirements listed in the foregoing, there is the further requirement that the power supply be available for use promptly. During ventricular fibrillation, blood circulation ceases and physiological damage may be minimized by holding the period of fibrillation to a minimum. Some delay is unavoidable in reaching a shock victim and in preparing for the defibrillation procedure. Additional time to make the power source available for use if required must be held to a minimum. Hence, a further requirement for the power supply is that it must be capable of being started or made to function within about 10 seconds and, preferably, within a shorter time period.

Current Supplies for Field Use

Fig. 1 shows the various arrangements of current sources that have been investigated and which are discussed in the following.

1. Consideration was given to the use of an a-c generator connected to a turbine driven by a compressed gas such as air or by hot gases from the burning of a propellant charge. The latter type of turbine has been developed for aviation use and it was found that it appears feasible to adapt a unit of this type to drive a generator for defibrillation use. This would require a development contract according to several manufacturers of this equipment. Estimate of the cost of development was $20,000 by one company, and $47,000 by another. Either of these expenditures would be expected to provide the first unit and succeeding units would be at considerably reduced cost. In one case, the cost of additional units was estimated at about $1,800 in lots of 10. The estimated weight of such a unit is 60 pounds.

Consideration was given to the use of compressed air to operate an air turbine instead of the turbine adapted to propellant-charge operation. Here, the weight of containers for the compressed air is a limiting factor unless extremely high gas pressure is used, in which event safety becomes a consideration. Pressure bottles would be bulky at moderate gas pressure and difficult to handle in the field. For this reason, the compressed-air unit was not given extended consideration. Possibly, a unit of this type could be developed which would meet weight and safety requirements.

2. Consideration was given to the use of storage batteries to operate a motor-generator set. The ordinary automobile-type storage battery was considered to be of too limited capacity to provide approximately 6 kw of electric output even though this might be sustained for a very short time. Consideration was given to another type of battery developed during World War II which requires immersion in water for activation. This battery has an indefinite shelf life when dry and, when immersed, provides high electric output for a single discharge. Difficulty is seen in testing defibrillation equipment employing this type of battery since a test of the equipment would require replacement of the battery and there may still be uncertainty as to the capability of the new battery.

Information was obtained on a new storage battery capable of extremely high discharge rates together with relatively low weight. This battery employs silver and zinc as plate materials and is capable of furnishing 1,350 amp for 30 seconds, or 630 amp for 5 minutes. A battery of these cells having an output of 24 volts is considered suitable for driving motor-generator devices. A battery of this type costs approximately $2,400 and weighs about 67 pounds.

Consideration has been given to the use of a fly wheel to assist the battery in meeting the high demand occurring at defibrillation. Such devices for storing mechanical energy have found limited practical applications but, in this instance, the weight of the fly wheel appears to be excessive for portability. The fly wheel becomes unnecessary in systems where use is made of the high discharge rate storage battery.

Having found the high-output storage battery which appears to be satisfactory for the proposed use, an investigation was made of the cost and weight of a motor-generator set to operate with 24 volts d-c on the motor and to have an output of 480 volts, 60 cycles a-c. It was found that such a motor-generator set could be purchased in the price range of $950 to $1,400. Thus, the cost of the silver-zinc battery and a suitable motor-generator set would be in the range of $3,350 to $3,800. The weight of the motor-generator set alone would be about 250 pounds; and total weight, including the storage battery, would be about 320 pounds.

3. Consideration has been given to the use of an a-c generator which is suitable for operation from the fan belt of a truck engine, from a power take-off on the truck, or by a separate engine. Such a generator is available having 3-phase output in 3-, 5-, and 10-kw ratings at 220 volts, 60 cycles per second. Tests on a 3-kw unit indicated that the single-phase overload capacity is sufficient to provide defibrillation current for the required time when operated at overspeed corresponding to a frequency of about 90 cycles per second and when using a transformer to step up the voltage to 480 volts. The 5-kw unit will meet defibrillation requirements at normal speed (60-cycles per second output) and, on single-phase load, this generator will supply 15 amp at 220 volts or 30 amp at 110 volts; the usefulness of the latter is described in the following. A transformer is provided to step up the voltage to 480 volts for defibrillation and also to reduce the voltage to 110 volts for other uses. A wheelbarrow-type base is contemplated together with a suitable gasoline engine to drive the generator such as a 2-cylinder 4-cycle engine. There is advantage in the wheelbarrow mounting in that the unit may be left at the work location while the truck proceeds to other operations. The cost of the complete unit is approximately $700 and the weight is approximately 530 pounds. If desired, a small hand winch can be installed on the truck to simplify movement of the unit into and out of the truck.

One matter of concern is the promptness with which this power source would be able to supply defibrillation current. To be satisfactory, the gasoline engine should start on the first attempt. Where the engine generator is a stand-by unit for defibrillation use only, there would be grave concern in regard to starting. This situation would be improved were the unit to be used frequently, such as where it would be called on to supply energy for routine field uses. A portable engine-generator set such as this could be used to operate miscellaneous hand tools, fans, lights, heaters, etc., and this might prove of great value in field operations. The set could also be used with a suitable rectifier to charge storage batteries for radio communication. Frequent use of the engine-generator set for these purposes would improve the starting reliability of the set should defibrillation use be required. There would be a good possibility that the unit would be in operation at the critical time.

4. Consideration was also given to the use of a generator of the type in which a permanent magnet is moved longitudinally through a series of coils to induce a limited number of cycles of alternating current suitable for use in defibrillation. An alternative would be to move the coils with respect to a fixed permanent magnet. In either case, the movable element could be operated by hand, by a spring, or by explosive charge. This type of device is not seen to have advantage over rotating devices such as the a-c generator already discussed. The latter has the advantage of being capable of providing more cycles of alternating current.

5. Consideration was given to the use of a vibrator-type inverter driven by a storage battery. The current requirements of such a device could not be met by the ordinary storage battery but the high-output storage battery previously mentioned could be used. There is uncertainty as to the ability of the contacts employed in the vibrator of the inverter to give reliable performance under such drastic operating conditions. For this reason vibrator-type inverters were given only passing consideration.

6. Consideration was given to the use of a multitapped transformer having input voltage taps for standard voltages up to 2,400 volts and an output winding to give 480 volts and 15 amp. The basis for using such a transformer may be found in the following statements which are believed to cover the facts:

a. Fibrillation would be unlikely to occur where the electric shock is from voltages in excess of 2,400 volts. In this connection, it is to be noted that fibrillation is induced by the passage of small currents (milliamperes) through the heart and, at voltages in excess of 2,400 volts, the current reaching the heart would be in excess of the values that produce fibrillation.

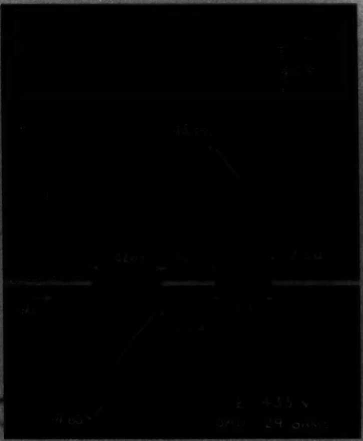

Fig. 2 (left). Capacitor discharge, 1-cycle type

Fig. 3 (below). Capacitor discharge, 2-cycle type

b. Shocks obtained from circuits at 2,400 volts and lower do not occasion current flows sufficient to open associated fuses or circuit breakers. Hence, the circuit that gave the shock would remain energized and be available after the shock.

c. A circuit exposed sufficiently to permit shock through accidental contact would be available to ground as an energizing source for the multitapped transformer.

Weatherproof transformers having input voltage taps at 120, 240, 480, and 2,400 volts and having an output voltage of 480 volts and current capability of 15 amps suitable for defibrillation use may be obtained for about $60. Such a unit would weigh about 50 pounds.

7. While the aim has been to obtain a 60-cycle output from the field power unit, consideration has been given to the design of a capacitor discharge type of device using radio *B* batteries as the current source. Devices of this type were built and tested. In one of these units, banks of capacitors were charged to 450 volts d-c and these were discharged through a programming switch to the electrode circuit. The switch in the first unit provided a discharge from one set of capacitors and then changed the connections to supply a discharge from another bank of capacitors in the opposite direction. Fig. 2 is an oscillogram of the discharge current through a dummy resistance load simulating the heart load. The results with this device in the defibrillation experiments were satisfactory when the delay between onset of fibrillation and application of defibrillation current was short (30 seconds). They were not as reliable for longer delay times as when 60-cycle current was used. This apparatus was then modified to provide 4 half-cycles of discharge, each succeeding cycle being of opposite polarity. Fig. 3 is an oscillogram of this type of discharge to the dummy load. The results with this modification were inferior to the 1-cycle device. It was concluded that simulated alternating current by capacitor discharge is inferior to a 60-cycle source.

8. Other types of energy sources are under consideration which require further development before their feasibility can be determined. These have not yet reached the stage to be included in this discussion.

Conclusions

The various current sources that have been discussed are indicated diagrammatically in Fig. 1. Following the order given in Fig. 1, the systems that appear to be most suitable for defibrillation in the field are as follows:

1. Turbogenerator unit driven by propellant charge. Units of this type would have the advantage of low weight (approximately 60 pounds). Their chief disadvantages are high development cost, minimum of $20,000, and relatively high unit cost, $1,800 each in lots of 10.

2. Motor-generator set using high-output storage batteries. The unit cost of this arrangement would be about $3,500 and the weight about 320 pounds.

3. Separate engine-driven generator. This unit would be available for defibrillation and routine uses such as battery charging, operation of power tools, lights, heating units, etc. The unit cost would be approximately $700 in single lots decreasing to about $645 in lots of 10. The weight of this unit is approximately 530 pounds.

4. The multitapped transformer having input voltage taps for 120, 240, 480, and 2,400 volts and an output winding capable of providing 480 volts at 15 amps. The cost of such a transformer is approximately $60 and the weight about 50 pounds. One disadvantage is that this equipment may not be immediately available for use as it requires connection to the source that administered the electric shock and this may be inaccessible or even undetermined at the time defibrillation is required. Where overhead lines are involved, the difficulty of connection is increased. The weight and cost considerations are quite favorable.

At the present time, it appears that the most practical unit for defibrillation is the separate engine-driven generator, item 3, which is used in routine field operations as well as for defibrillation. The matter of prompt starting is yet to be determined in relation to the requirements of defibrillation.

Supervisory Control and Associated Telemetering Equipment—A Survey of Current Practice

AIEE COMMITTEE REPORT

SUPERVISORY control had its inception in the early 1920's. The use of supervisory control increased gradually in the succeeding years as more operating companies became acquainted with it and the benefits that could be realized by its use. Its use has increased at an accelerated rate since the end of World War II, indicating a greater trend toward centralized control of power systems. The availability of improved telemetering equipment to operate in conjunction with supervisory control has accelerated the use of both because it has made possible bringing control, indication, and metering of distant substations and equipment to a centralized control point. This has resulted in reduced operating costs and improved system efficiency.

Questionnaire

A working group of the Automatic and Supervisory Control Subcommittee prepared a questionnaire regarding employment and characteristics of supervisory control and telemetering systems in use. This questionnaire was distributed early in 1953 to 119 representative operating companies throughout the United States. Eighty replies to the questionnaire were received. The purpose of the questionnaire was to determine for the benefit of both manufacturers and users the present relative usage and the possible trend of usage of supervisory control and telemetering and characteristics of existing equipments.

QUESTION 1

The first question asked the users to list the various types of stations with and without supervisory control, as shown in Table I. The purpose was to determine

Microwave	61	5,234	4.0	450	85.7

Table III. Size of Unattended Automatic and Unattended Supervisory Stations

		Time to Get to Station			
	Range, Kilovolt-Amperes	Minimum, Minutes	Maximum, Minutes	Average, Minutes	No. of Replies
Largest unattended automatic station in use	1,250 to 200,000	15	75	25.5	77
Largest unattended automatic station considered feasible	3,000 to 300,000				43
Largest supervisory controlled station	900 to 210,000	15	60	23.3	78
Largest supervisory controlled station considered feasible	10,000 to 800,000				36

the extent of usage of supervisory control and telemetering for various applications.

The following definitions were established as a guide for answering this question:

1. A bulk power station transforms power from the transmission system to the subtransmission circuits which supply the distribution stations. The transmission circuits transmit power from the generating stations to the bulk power stations and may also transmit power between generating stations.
2. A distribution station consists of a source of supply to the primary circuits which feed distribution transformers or industrial loads. The industrial or network substations should not be included. The distribution station may or may not involve a transformation.
3. A switching station permits switching of circuits (usually at the transmission voltage level) and there are no transformations.

Table I shows the use of supervisory control as reported by 77 users involving approximately 935 supervisory systems. The majority of supervisory and telemetering is used in control of a-c substations with the highest percentage on bulk power and switching stations. Column 5 shows the total percentage of substations using supervisory control (total of columns 3 and 4). 31.3 per cent of the switching stations used supervisory control. On an over-all basis 6.7 per cent of the stations or substations were reported as supervisory controlled. Since the questionnaire was not sent to transportation companies, the information obtained on power rectifiers, synchronous converters, and motor generators is less than that obtained for the other applications.

QUESTION 2

The second question asked the users to list distances and types of channels in use for supervisory control and telemetering. Table II is a tabulation of distance and types of channels used with supervisory control and telemetering by 75 users. It shows that the majority of channels are line wire but that power-line carrier channels are very numerous and represent by far the largest number of channel miles. This is to be expected as supervisory systems are applied to more and more distant stations. The number of microwave channels show a favorable reception considering the short time that they have been available, and the indications are that this type of channel is being used for longer distances than any other types of channels.

QUESTIONS 3 AND 4

The users were asked to state the kilovolt-amperes of the largest unattended automatic station and the largest supervisory controlled station on their systems, the largest they would consider for each, and the time required for an operator to reach the station. Table III shows the range of replies to these questions. The tabulation indicates that automatic and supervisory control is already in use to control fairly large stations or substations. It also indicates that users have realized sufficient reliability and economy of operation with supervisory equipment to warrant its being applied to control much larger stations and substations.

QUESTION 5

Users were asked whether or not they considered automatic or supervisory controlled stations as reliable as those manually operated. Out of 75 replies, 79 per cent answered "yes" and 21 per cent answered "no." Out of 75 users, 4 replied that automatic or supervisory controlled stations had been changed to manual for the following reasons:

1. Two stations were temporarily changed because of policy and will later be restored to supervisory control.
2. One user discontinued use in urban areas as he could not tolerate delays.
3. One station was changed because of obsolete equipment.
4. One station outgrew circuit-breaker ratings with reclosers.

It is noted that only one user reported discontinued use of supervisory control for a reason which might be a reflection against the equipment. Details of this case were not reported by the user.

QUESTION 6

Users were asked to check the types of telemeter readings (such as kilowatts) they used with supervisory control and to

Table IV. Use of Telemetering with Supervisory Control

	Number of Users Using	
	Continuous Readings	Selected Readings
Kilowatts	32	29
Kilovars	28	25
Bus voltage	23	38
Feeder current	5	24
Position	12	29
Water level	10	8
Kilowatt-hours	11	11

list whether the readings were continuous or selected. Table IV shows the number of users of supervisory using the various types of telemeter readings. The majority of use is in reading kilowatts, kilovars, and voltages. Although not apparent from the table, it was found that out of 79 users of supervisory control, approximately 81 per cent use telemeter readings of some sort. 50 per cent of the telemeter users employ both continuous and selected readings. Approximately 30 per cent of the telemeter users employ selected readings only, while approximately 20 per cent use continuous readings only. This table shows that telemetering has become of major importance in the use of supervisory control and is an important factor responsible for its rapid growth.

Question 7

Users were asked to indicate whether or not automatic synchronizing or synchronism check is used on tie-line circuit breakers closed automatically or by supervisory control. Out of 78 users of automatic or supervisory controlled stations, approximately 76 per cent of the users employ automatic synchronizing or synchronism check equipment. This indicates that automatic synchronizing or synchronism check equipment is also an important adjunct to supervisory systems and that supervisory is extensively used to close tie-line breakers and connect a-c generators to the system.

Question 8

Users were asked to list the source of power used for supervisory control. Out of 77 users of supervisory control, 74 use batteries for control power. Eighteen of these users also have supervisory control operated from a-c station service. Of the 74 users employing batteries for control power, approximately 36 per cent use both station control batteries and separate supervisory control batteries, 39 per cent use station control batteries only, and 25 per cent use separate control batteries only. This indicates that battery control power is most extensively used primarily because of its reliability. However, it also indicates that in some cases it is preferable from the user's standpoint to use a-c station service as a control power source. Some such installations use an emergency supply such as a motor generator operated from a battery to generate alternating current for the supervisory equipment in case of failure of the normal a-c station service. The use of separate control batteries for supervisory control reduces the possibilities of grounds in the control circuit with the resulting troubles.

In some cases, it is easier to maintain separate supervisory system batteries at constant potential at both the master and remote station because of the steady drain imposed by supervisory equipment devices. Most supervisory systems are now available for operation on 48 or 125 volt d-c. This permits the use of the station control battery in many cases which, of course, reduces the initial battery costs and the resultant maintenance and replacement costs.

Conclusion

The replies to the questionnaires distributed indicate that supervisory control and associated telemetering is now being used very extensively by operating companies. The design of supervisory equipment, its utilization of modern telemetering equipment, and its adaptation to a variety of channels to cover great distances have kept pace with the requirements of the power industry. It is expected that the usage of supervisory control will increase considerably in the future because of its versatility and the recognized advantages of centralized control for efficient system operation.

Eccentricity, Vibration, and Shaft Currents in Turbine Generators

L. T. ROSENBERG
MEMBER AIEE

THE operation and maintenance of modern high-speed turbine-driven generators require a thorough knowledge of their construction, as well as the ability to recognize the symptoms and understand the causes of impending injury and failure. In the preparation of the proposed AIEE Guide for the Operation and Maintenance of Turbine Generators, it was decided certain topics that do not readily fall into any major classification could be grouped together into a miscellaneous section. Under this heading the Working Group for the Preparation of Operating and Maintenance Guide for Turbine Generators has listed:

1. Eccentricity of rotor in stator.
2. Axial position of rotor with respect to stator.
3. Vibration.
4. Shaft currents and bearing insulation.

It was further decided that the substance of this section of the proposed guide be submitted to the membership in the form of suitable papers. It was hoped this would bring forth discussions from among operators as well as manufacturers that could be incorporated into the proposed Operating Guide before final publication.

This paper discusses the four subdivisions of the miscellaneous section from the standpoint of diagnosis, causes, corrective measures, and preventive maintenance. In order to be applicable to air-cooled as well as hydrogen-cooled machines and both bracket-bearing and pedestal-bearing types, the construction features of the four largest American turbine-generator manufacturers were studied, and the recommendations of each relating to these topics were carefully considered. No attempt has been made to include the steam turbine except in so far as it may be a contributing factor to generator behavior.

Eccentricity of Rotor in Stator

The initial assembly of a turbine-generator unit involves careful alignment of the generator rotor with the turbine

---

Paper 55-121, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing December 6, 1954.

The author wishes to acknowledge the many helpful suggestions and the instruction book material received from the members of the AIEE Working Group for the Preparation of Operating and Maintenance Guide for Turbine Generators.

spindle, as well as accurate positioning of the stator with respect to the rotor. Eccentricity of the rotor is more serious on 4-pole machines than on 2-pole units, because the flux in the region of the small gap is in parallel with that in the region of the long gap rather than in series and hence subject to more variation per revolution. Even in 2-pole units, however, the flux density wave becomes higher near the pole center as it approaches the region of the small gap and the magnetic pull is appreciably greater in this region. In addition to the pulsating unbalanced magnetic forces, the changes in flux distribution cause induced currents in rotor winding, wedges, and surface, and circulating currents between parallel stator circuits with consequent increased losses and temperatures. Excessive inequality in the gap can also adversely affect the fringing fluxes at the core end region and may result in abnormal local temperatures in clamping plates or retaining rings. The maintenance of accurate centering is also important to be sure of maintaining uniform clearances at oil wipers, fans, baffles, etc., where tolerances are often small.

Concentricity is initially established by careful measurement of the air gap in at least four positions at each end of the generator. The procedure and allowable tolerances will vary somewhat depending on the air-gap length, the number of poles, whether the unit is air- or hydrogen-cooled, and whether the rotor is supported in pedestal- or bracket-type bearings.

In some bracket-bearing machines, the adjustment of the air gap as well as the clearances at oil wipers, baffles, seals, fan shrouds, etc., is accomplished at the factory prior to shipment. In other types, these adjustments may be made or rechecked during installation of the unit, and should preferably be done under the supervision of the manufacturer's erection engineer. In any case, the procedure and allowable tolerances recommended by the manufacturer should be followed in the initial installation as well as in subsequent reassemblies.

Once properly centered, the rotor is not likely to shift suddenly except in the case of accident. With separately supported pedestal bearings, settling or growth of the foundation or grouting over an extended period may disturb concentricity, as well as the alignment between rotor and turbine spindle. Abnormal wear of the babbitt will also tend to bring about these same results. Checking the gap for uniformity at regular inspection periods is therefore advisable and can often be done quickly by tapered feelers, thickness gauge, or pin gauge either in the air gap or between rotor bearing fit and outer frame ring bore if the position of the latter is previously determined relative to the stator inner frame bore. If measurements are made in the gap, care must be exercised to be sure the gauge is in contact with a tooth rather than a slot wedge and far enough from the core end to avoid the tapered or stepped end laminations if employed.

Axial Position of Rotor with Respect to Stator

The rotor should be reasonably well centered axially with respect to the stator under all operating conditions. Appreciable asymmetry not only produces an end thrust but can seriously affect the end fringing flux and produce abnormal local heating of the fingerplates and retaining rings.

If the generator has bracket-type bearings supported from the end covers, the correct axial location of the rotor can usually be obtained by an adjustment relative to the bearing center lines. These are permanently located in relation to the stator core and yoke by the machined end cover fits against the stator. In this type, the fan shrouds, seals, baffles, oil wipers, etc., may sometimes be adjusted at the factory before shipment to suit the bearing positions and in such cases should need no further checking. Adequate provision is usually made for axial movement of the coupling due to thermal changes in the turbine, and for any additional expansion of the rotor when the unit is loaded, as well as for any necessary axial clearance for disengaging the coupling.

For machines with separate pedestal-type bearings initial axial centering is often accomplished after the rotor has been lined up and coupled to the turbine by adjustment of the stator position on the base plate. If this had not been done previously at the factory, or if for any reason the stator was not suitably dowelled or keyed to the base plate, axial centering must be done when the unit is installed.

Since the method of adjustment and permissible tolerances depend upon individual design details, the manufacturer's recommendations should be followed for each unit. Once the correct stator location has been established, subsequent checking of axial positioning is seldom necessary unless either the thrust bearing or the stator has been moved from its initial setting. The adjustment of fan shrouds, baffles, etc., however, may be necessary whenever they are disturbed, or after the rotor is removed and replaced.

When the axial centering of the rotor must be rechecked, measurements should be made between stator core ends and some reference point on the rotor such as the outer end of the retaining rings if they are equally spaced from the rotor body. Measurements at several points around the periphery are recommended to allow for uneveness in the punchings.

Vibration

The vibration of a turbine-generator unit may originate from a number of widely different causes. The most common source of rotor vibration arises from physical dissymmetries in the rotor when built that result in nonuniform weight distribution around the geometric axis. To overcome roughness from this source turbo-generator rotors are carefully balanced at the factory before shipment. Touch-up balancing is often necessary after installation because of the influence of the foundations and of the turbine spindle if solidly coupled. Other causes of rotor roughness have been traced to thermal or magnetic sources and to the inequality in rotor stiffness in the direct and quadrature axes, as well as to improper adjustment of bearing clearances, oil whip, and other factors related to lubrication.

Measurement of rotor vibration is most commonly made at the bearings. There are several types of instruments in general use that accurately measure or record the amplitude of movement. Experience has shown that a single set of permissible bearing vibration amplitudes cannot be established that would safely cover all types and ranges of ratings. Consequently, the manufacturer's recommendations should be followed in each case.

Vibration in the stators of 2-pole generators sometimes results from the magnetic pull between rotor and stator in the air gap, the force being greater in the direct axis than in the quadrature axis. The rotating magnetic pull tends to deform the stator elliptically, thus creating a double frequency component of stator vibration. Adequate rigid bracing to limit the magnitude of the core distortion on large 2-pole machines proved impractical from the standpoint of shipping clearances, stator weight, and appearance. In most large modern 2-pole machines the core vibration is therefore usually isolated from the outer wrapper and foundation by means of some form of flexible support.

If the core is tightly clamped from the

ends, the laminations will be supported as a continuous ring that will have a natural frequency well above the 120-cycle forced frequency. Under this condition the amplitude of the core vibration will usually be well within safe limits, and little or no objectionable double frequency vibration is likely to be transmitted to the foundations. Occasionally, some parts of the outer wrapper plate or lagging may resonate at or near 120 cycles and the acceptable vibration amplitude of these parts will in most cases depend upon their manner of support or the nuisance value in the form of unpleasant noise, provided the core vibration is known to be safe. Proportions of 4-pole stators have been such that core vibration has seldom been troublesome.

The sudden appearance of new vibration or an increase in existing amplitude may be of greater significance to the operator than the steady continuous type of vibration. For this reason a history of vibration amplitudes is believed desirable for all machines. One of the first signs of short-circuited rotor turns may be increased rotor vibration. Removal of excitation will often indicate whether the effect is electromagnetic. Measurement of rotor resistance is seldom a reliable indication unless the exact temperature is also known. If the rotor has a temperature recorder the chart should be examined for indications of a sudden drop in rotor resistance at the time, vibration appeared. The rotor impedance with 110 volts, 60 cycles, applied to the rings is sometimes useful for detecting rotor turn short circuits provided an initial reading with no short-circuited turns is available for comparison. Most rotors will not take more than 5 to 10 amperes at 110 volts and hence can be tested from the lighting circuit if the rotor winding is not grounded.

Unlike short-circuited turns in the stator, short-circuited rotor turns do not necessarily require reinsulation immediately if a satisfactory balance can be achieved. Rotors have been known to operate for years with a few short circuits between successive turns in one or more coils. Experience has shown that short-circuited rotor turns are not usually progressive in nature and are more apt to reduce the temperatures in their respective coils than increase them. Of course, they do require more excitation amperes, and hence the rotor temperature as a whole is increased even though a temperature indicator may show the reverse.

If short-circuited turns cause a thermal unbalance, the vibration will vary with temperature and hence will lag any increase in excitation by the length of time required for heating to occur. If variation from the cold to the hot condition is not too great, weight adjustments can sometimes be made to keep the amplitude entirely within a satisfactory range for all temperatures.

Location of the slots containing short-circuited turns or coils may be possible in solid rotors without retaining ring removal by measuring the leakage flux across the top of the slot wedge with an alternating voltage applied to the collector rings and comparing the readings for the various slots. With nonmagnetic wedges a single short-circuited turn out of 20 or 30 turns will reduce nearly 50 per cent the alternating voltage induced in an exploring coil held above the slot wedge. Slots with magnetic wedges should be compared with each other as their leakage flux is quite low. An oscilloscope is often useful to measure the low exploring coil voltage if a 110-volt a-c supply is used across the collector rings. Other means are sometimes also used such as an a-c potentiometer. After location of the slots affected, thermal balancing may be possible by partial restriction of the ventilating ducts in the region of these slots. If axial ducts are not provided or accessible, the use of paint or other surface treatment for thermal balancing may be possible but this would probably be a trial and error process.

Increased rotor vibration could also indicate a displacement of rotor coil blocking or physical damage to the shaft or fans. A fiber baffle rubbing the shaft at one point has been known to cause severe shaft vibration. Such cases are unaffected by the removal of excitation and after tripping often continue during retardation.

A sudden appearance of stator vibration or noise might indicate high voltage, unbalanced load, or a loosening of the core to a point where some of the laminations have ceased to act as a rigid ring. It could also mean a loosening of some parts, either internal or external, that have become resonant at the frequency of the applied force or are being rattled about by the ventilating gas. In double-winding machines, a characteristic noise can be heard clearly when load is suddenly removed from one of the windings.

The appearance of vibration has also been traced to such external factors as the shifting of the foundation because of settling or thermal changes, coupling misalignment or uneven wear, roughness transmitted from the turbine spindle, unequal expansion of turbine and generator bearing supports, and it even has been traced to other machines in the same power plant. As an example of remotely induced vibration, internal inspection of a 35,000-kw hydrogen-cooled turbo-generator once revealed a continuously vibrating cooler tube while the unit was at rest with its rotor removed. The source of vibration was found to be a compressor operating in the basement of the power plant. Another interesting case consisted of a vibrating noise which after months of speculation was finally traced to a loose valve handle below the generator that was resonant to the minute vibration of the shell.

Shaft Currents and Bearing Insulation

The most common cause of induced shaft voltages is the inequality in reluctance of the parallel flux paths linking the rotor and the consequent pulsations in this component of flux. If both bearings are in electric contact with each other through a frame or base plate, substantial currents may flow through bearing oil films and may damage the shaft journals and the babbitt surface, as well as gears or other metallic parts in contact with the rotor or turbine spindle. Under certain conditions sludging of the lubricating oil may also occur.

By suitable combination of partings, lamination segments, and number of poles, the voltages from this source can sometimes be minimized, but the choice of these design details is greatly restricted in turbogenerators. Consequently, the outboard end of the rotor is usually insulated from ground, including the bearing, all piping connections, exciter coupling or bearings, hydrogen seal, etc.

Shaft currents can also result from a magnetized shaft, bearing pedestal, or end cover or from windings or end connections that produce axial flux in the rotor. The currents induced from these sources do not always flow from bearing to bearing, but can flow from shaft to babbitt at one end of the bearing and back again at the other. The bearing insulation will not prevent this type of circulating current. Fortunately, this condition is not common and the currents from it are not usually very great. It can often be detected by the characteristic scratches appearing at the extremities of the bearing journal, and its correction is usually possible by demagnetization of the affected parts. Cases of magnetized shafts, bearings, and end covers have been known to result from the dryout of stator windings using direct current or from double ground faults in rotors.

Bearing currents have also been found

to originate from electrostatic charges generated within the steam turbine. Pitting or abnormal wear of worm gears as well as objectionable radio and television interference have been traced to this source. The remedy in such cases is a grounding brush somewhere on the shaft or spindle.

The use of grounding brushes at both ends of the unit to short-circuit the shaft currents induced along the shaft has not been uniformly effective since the brushes themselves often have an appreciable contact potential drop. Damage to gears near the front end of the turbine has been reduced, however, by installation of a grounding brush near the gear.

With pedestal-type bearings or with bracket bearings where the outboard bracket is insulated from ground, there are various means to check the insulation of the outboard bearing while the unit is running. Perhaps the simplest consists of two successive measurements of voltage using an a-c d-c millivoltmeter, the first from a sliding contact on the shaft to ground at the outboard end of the rotor, and the second from the pedestal (or insulated bracket) to ground with a dead short circuit from a sliding contact on the shaft to the pedestal (or insulated bracket). If the bearing insulation is satisfactory both readings will be alike; if not, the second will be lower than the first.

To check the insulation of pipe joints while the unit is running, a couple of dry cells or a storage battery may be connected from the pedestal (or insulated bearing bracket if bracket type) to a point on the pipe 2 or 3 feet beyond the insulated flange. A d-c millivoltmeter connected across the 2- or 3-foot length of pipe between flange and battery connection will indicate whether any current is flowing through the insulated joint.

If the bearing is mounted within the end cover the insulation is sometimes located between the bearing pads and the bearing or between the bearing ring and end shield. In hydrogen-cooled machines seal insulation may be located between the seal and either the vents, brackets, or end shields. No separate seal insulation or bearing insulation is necessary if the bracket itself is insulated. In some types, oil seals are also insulated, and in some cases both hydrogen seals or both ends of the rotor may be insulated rather than only one. The insulation of such enclosed parts should be checked individually as each part is assembled. The insulation of thrust-bearing-type seals may be rechecked by pressing the seal ring back away from the shaft flange before the top half of the bearing is assembled. The main bearings and circular-type seals may be rechecked by lifting the rotor a few mils and sliding a thin sheet of insulation under the journal. Care must be exercised to avoid damaging oil wipers or other stationary parts by excessive lifting of the rotor. The condition of insulation with either bracket- or pedestal-type bearings can sometimes be checked while the machine is running by touching a grounded wire to the shaft to see whether a spark occurs. The absence of sparking may be an indication of faulty insulation unless the machine is known to be entirely free from shaft voltages.

The most common causes of faulty bearing or seal insulation are metallic chips or slivers in bolt holes or across small internal clearances. Embedded thermocouples, graphite or paint on insulating material or pipe flanges, and low resistance gasket material, as well as other forms of dirt, moisture, or foreign matter, have also been found to cause trouble.

Analysis of Fault Currents for High-Voltage Circuit-Breaker Interruption

MARTIN J. LANTZ
MEMBER AIEE

THE most important factor in the operation of a circuit breaker under fault conditions is the current the breaker must interrupt. The purpose of this paper is twofold: To indicate and discuss the factors involved in the appraisal of interrupting duty of existing system circuit breakers; and to discuss relative magnitudes of currents for the different types of faults that a breaker must interrupt.

The basic or symmetrical rms current that the breaker must interrupt is calculated by the standard method of symmetrical components. Circuit conditions that may modify these basic current values are asymmetry of the current or d-c offset which increases the basic current value, and fault resistance which decreases the basic current.

The standard method of fault calculation is based on the AIEE general method which assumes all source voltages in phase, one per-unit internal voltage, subtransient machine reactance, and equality of positive- and negative-sequence reactance. Application of these data to the standard equations produces a current approximately equal to the theoretical current at time zero. A-c decrement is normally neglected for high-speed circuit breakers but is probably in the maximum order of 6 to 8 per cent for times of 3 to

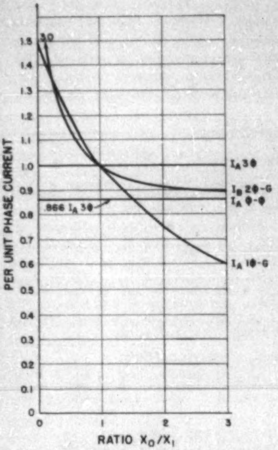

Fig. 1. Relationship of total fault current for various types of fault as a function of the X_0/X_1 fault-impedance ratio

5 cycles near generating plants.

The Appendix shows the standard equations and connotation for the calculation of the basic fault currents. These are the total currents to the fault. For ground faults, the total fault current I_g is equal to the summation of the phase currents to the fault. The circuit residual current is the summation of the zero-sequence currents in the three phases of the circuit and is equal to $3I_0$; however, this current does not flow in a single conductor to be interrupted by the circuit breaker except for a radial circuit to the fault point. For the majority of faults, the actual current to be interrupted by the first opening breaker is the phase current or current flowing through the conductor. This current is a combination of the sequence currents which are distributed according to their own network impedances. To determine the current to be interrupted by the first opening breaker, it is necessary to calculate the phase current through it by combining the various sequence currents in proper order. The second opening breaker for a 2-terminal circuit has a duty equal to that of a radial line breaker.

Fig. 1 shows the relationship of total fault currents for the various types of fault. If $X_1=X_2=X_0$, all faults are of equal magnitude except the phase-to-phase fault which is equal to 0.866 times the others. If X_0 is greater than X_1, the total phase current for the ground faults is less than the 3-phase fault current, as shown in the curve. If X_0 is less than X_1, the total phase current to the ground faults is greater than the 3-phase fault current with ideal limits of three times greater for the 2-phase-to-ground and 1.5 times greater for 1-phase-to-ground fault. The practical limits are approximately 1.35 to 1.4 corresponding to a ratio of X_0/X_1 of 0.2. From the curve it is apparent that the most severe total fault current results from either a 3-phase or phase-to-ground fault except for extreme low ratios of X_0/X_1.

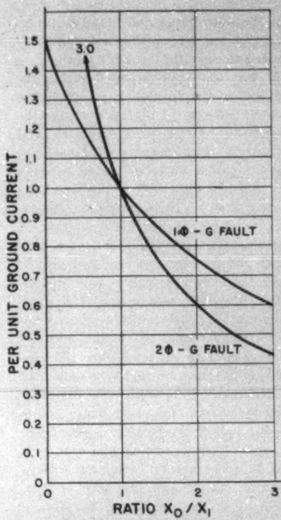

Fig. 2. Relationship of total residual fault current for single- and double-phase-to-ground faults as a function of the X_0/X_1 fault-impedance ratio

Fig. 2 shows the relationship of total residual or ground currents for the two types of ground faults. The same current limits are reached as for the phase currents for the theoretical lower ratio limit of zero. It will be noted that for the 1-phase-to-ground fault the total phase current and ground fault curves are equal.

In circuit-breaker application, it is the phase current which is interrupted in all cases. In special cases such as radial circuits, the phase current equals the residual or ground current for ground faults, since the radial current is the total fault current. This is not true when fault current is contributed from more than one path to the fault. In the appraisal of the amount of phase current interrupted by the circuit breaker, the branch current which does not go through the breaker to the fault is not interrupted and should be subtracted from the total value. This is a simple matter for the phase faults but becomes more involved for the ground faults. The phase-current distribution must be determined for the bus fault and the branch currents subtracted to determine the appropriate circuit-breaker current.

For ground faults, the ground-current magnitude is a function of all three impedance networks but its distribution is a function of the zero-sequence impedance network only. The determination of the phase-current distribution requires the sequence-current distribution of both the positive- and zero-sequence networks. The following equations may be used to determine the phase-current distribution from the sequence-current distribution.

1-phase-to-ground fault

$$\text{Branch phase current } I_A=2\times\text{total } I_0\times\frac{\text{branch } I \text{ 3-phase fault}}{\text{Total } I \text{ 3-phase fault}}+\text{branch } I_0$$

2-phase-to-ground fault

$$I_B \text{ branch phase current} =\frac{I \text{ branch 3-phase fault}}{I \text{ total 3-phase fault}}\left(\frac{a^2}{K_1}-aK_2\right)-\frac{I_0 \text{ branch 1-phase-to-ground fault}}{I_0 \text{ total 1-phase-to-ground fault}}(K_3)$$

where

$$K_1=X_1+\frac{X_1X_0}{X_1+X_0}$$

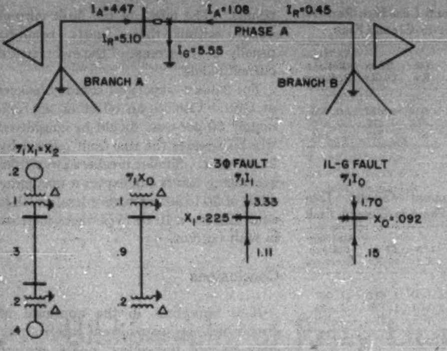
$$K_2=\frac{1}{X_1+2X_0}$$

$$K_3=\frac{X_0}{X_1^2+2X_1X_0}$$

$$a=-0.5+J.866$$
$$a^2=-0.5-J.866$$

The values of reactance are the total system sequence reactance to the point of fault. While the foregoing equations look cumbersome, they reduce down to simple calculations when the numerical values are known for a given location.

To determine the phase-current distribution for a 2-phase-to-ground fault, the data required are the 3-phase fault-current distribution and total positive-sequence impedance for a 3-phase fault and the zero-sequence current distribution any total zero-sequence impedance for a 1-phase-to-ground fault. This assumes that X_1 and X_2 are equal. The impedance constants may be computed and applied to the equation to evaluate the branch-faulted phase current for a 2-



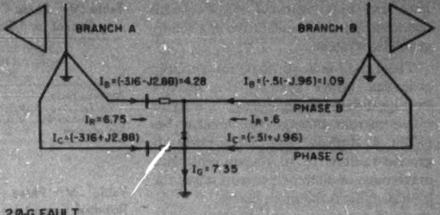
1Φ-G FAULT

$$\text{BRANCH } \Phi \text{ CURRENT} = 2 \times \text{TOTAL } I_0 \times \frac{\text{BRANCH } I\ 3\Phi \text{ FAULT}}{\text{TOTAL } I\ 3\Phi \text{ FAULT}} + \text{BRANCH } I_0$$

$$I_A \text{ BRANCH A} = 2 \times 1.85 \times \frac{3.33}{4.44} + 1.70 = 4.47$$

$$I_A \text{ BRANCH B} = 2 \times 1.85 \times \frac{1.11}{4.44} + .15 = 1.08$$

Fig. 3. Single-line-to-ground fault, phase-A current



2Φ-G FAULT

$$I_B \text{ BRANCH } \Phi \text{ CURRENT} = \left(\frac{a^2}{k_1} - ak_3\right)\frac{I \text{ BRANCH } 3\Phi \text{ FAULT}}{I \text{ TOTAL } 3\Phi \text{ FAULT}} - \frac{k_2 I_0 \text{ BRANCH } 1\Phi\text{-G FAULT}}{I_0 \text{ TOTAL } 1\Phi - \text{G FAULT}}$$

$$k_1 = .225 + \frac{.225 \times .092}{.317} = .29$$

$$k_2 = \frac{1}{.225 + .184} = 2.45$$

$$k_3 = \frac{.092}{.225^2 + 2 \times .225 \times .092} = .99$$

$$\left(\frac{a^2}{k_1} - ak_3\right) = \frac{-.5 - J.866}{.29}\,(+.5 - J.866)\,.99 = -1.23 - J3.84$$

$$I_B \text{ BRANCH A} = \frac{3.33}{4.44}(-1.23 - J3.84) - \frac{1.70}{1.85} \times 2.45 = -3.16 - J2.88 = 4.28$$

$$I_B \text{ BRANCH B} = \frac{1.11}{4.44}(-1.23 - J3.84) - \frac{.15}{1.85} \times 2.45 = -.51 - J.96 = 1.09$$

Fig. 4. Two-phase-to-ground fault, phase-B and phase-C current

phase-to-ground fault which is the current to be interrupted by the circuit breaker.

An example of a simple computation is shown in Figs. 3 and 4 equation. These represent a generator and high-side grounded-neutral transformer on each end of a single-circuit transmission line. The fault is assumed on the line side terminals of the circuit breaker near the branch A bus. Assumed reactance and calculated current values are shown in per-unit values. The basic data required to determine the phase-current distribution for both single- and double-phase-to-ground faults are the phase-current (I_1) distribution for a 3-phase fault and the zero-sequence current (I_0) distribution for a single-phase-to-ground fault. These basic calculated data are shown. Application of the conversion equation permits calculation of the faulted phase currents for both types of ground faults. The residual currents $3I_0$ are also shown for comparative purposes as is the total fault current I_g. The X_0/X_1 ratio of this example is 0.41. From the curve for this ratio, a lower total phase current and a greater total ground current is to be expected for the 2-phase-to-ground fault compared to the 1-phase-to-ground fault. This is shown by the calculated values.

System Circuit-Breaker Analysis

A survey of 334 high-voltage circuit breakers on the Bonneville Power Administration solidly grounded system show the following relative interrupting duties for 3-phase and single-phase-to-ground faults. This study includes all circuit breakers of the main system except the circuit breakers at the Bonneville, Hungry Horse, and Grand Coulée generating plants. Table I shows the type of faults producing the most severe circuit-breaker duty and the number of breakers involved. Only 3-phase and single-phase-to-ground faults were studied since their duties were the most severe. The data indicate that about an equal number of the system breakers will receive their greatest duty from each type of fault. Also the data show that the relative position of the line, transformer, or other breakers does not modify the general picture of distribution of duty and type of fault. Other positions include shunt capacitor, bus tie, and bus-sectionalizing circuit breakers.

Table II shows the average and maximum ratios of phase current through the breaker for a single-phase-to-ground fault to the phase current through the breaker for a 3-phase fault where the ground fault was more severe. Table III shows the average and maximum ratios of phase fault to phase current through the breaker for a 3-phase current through the breaker for a single-phase-to-ground fault where the 3-phase fault was more severe. The 57-to 69-kv values are omitted from the all-breakers average because the grounding banks and remote ground sources result in high-fault zero-sequence imped-

Table I. Number and Type of Fault Producing Most Severe Circuit-Breaker Duty

	230 Kv		115 Kv		57 to 69 Kv	
	3-Phase Fault	1-Phase-to-Ground Fault	3-Phase Fault	1-Phase-to-Ground Fault	3-Phase Fault	1-Phase-to-Ground Fault
Line breakers	29	34	64	55	17	23
Transformer breakers	10	15	12	14	6	8
Others	8	6	15	14	2	2
Total	47	55	91	83	25	33

Table II. Ratio of I_ϕ Current for Ground Fault to I-Phase Current for 3-Phase Fault

	230 Kv	115 Kv	57 to 69 Kv	All High-Voltage Circuit Breakers
Average ratio	1.414	1.184	1.166	1.167
Maximum ratio	1.488	1.538	1.348	1.538

Table III. Ratio of I_ϕ Current for 3-Phase Fault to I_ϕ Current for Ground Fault

	230 Kv	115 Kv	57 to 69 Kv	All High-Voltage Breakers*
Average ratio	1.132	1.198	1.946*	1.170
Maximum ratio	1.400	1.563	5.000*	1.563

* These values are high because of grounding banks and remote ground-current sources.

ance and high ratios of X_0/X_1. This condition is not representative of a solidly grounded system.

These data indicate that, for a solidly grounded power system, the relative average differential in severity of duty or phase current through the breaker between a 3-phase and single-phase-to-ground fault is 13 to 19 per cent with maximums of 40 to 56 per cent when the 3-phase fault is the more severe.

The circuit-breaker duty is determined by the actual phase current passing through it to the fault. This is not the residual current for a ground fault except for the case of a radial position with no backfeed of either positive- or zero-sequence currents. Erroneous breaker duties will result when residual currents are used to determine breaker duties. A study of the fault currents where the ground fault exceeded the 3-phase fault indicates the relationship between phase currents and residual currents present in the breaker positions; see Tables IV, V, and VI.

These data indicate that unless the phase current is used for determining the breaker duty, for single-phase-to-ground faults, the average breaker duty calculated would have been 9.5 per cent too great with a maximum error of 43 per cent for approximately half the system breakers and 5.7 per cent too small with a maximum error of 44.6 per cent for the other half. It also shows that for 32 of the systems breakers the phase current on the average was 5.8 per cent greater than either residual current for a 1-phase-to-ground fault or phase current for a 3-phase fault with a maximum of 18.3 per cent greater. These data may or may not be important in the application of new circuit breakers but they are important in appraising the duties to be expected of existing system breakers. Phase current through the circuit breaker should always be used to determine the actual circuit-breaker duty. The main purpose of this paper is to discuss the factors involved in the appraisal of interrupting duty of existing system circuit breakers. The application of new breakers would be based on the same fundamental data but adequate allowance must be made for system expansion. A study of existing breakers on an expanding system should be made periodically to make sure that they may not be seriously overstressed by fault.

Table IV. Phase Current Less Than Residual Current for 1-Phase-to-Ground Fault

	230 Kv	115 Kv	57 to 69 Kv	All High-Voltage Breakers
Average ratio I_ϕ/I_g	0.904	0.912	0.885	0.905
Minimum ratio	0.626	0.675	0.570	0.570
No. of cases	56	87	25	168

Table V. Phase Current Greater Than Residual Current for 1-Phase-to-Ground Fault

	230 Kv	115 Kv	57 to 69 Kv	All High-Voltage Breakers
Average ratio I_ϕ/I_g	1.098	1.050	1.012	1.057
Maximum ratio	1.554	1.454	1.136	1.554
No. of cases	46	87	29	162

Table VI. Phase Current Greater Than Either Residual Current for 1-Phase-to-Ground Fault or Phase Current for a 3-Phase Fault

	230 Kv	115 Kv	57 to 69 Kv	All High-Voltage Breakers
Average ratio I_ϕ/I_g or $I_{3\phi}$	1.056	1.080	1.035	1.058
Maximum ratio	1.109	1.183	1.136	1.183
No. of cases	15	9	8	32

When the maximum symmetrical current possible for the breaker to be required to interrupt is determined, there are still other factors to be considered. Normally zero-fault resistance is used for ground-fault calculations; however, tower-footing resistance may limit the possible fault current reducing the breaker duty.[1] In appraising the possible fault duty of a circuit breaker, probability factors should be considered. One factor is the exposure involved. The amount of physical exposure to fault for a bus sectionalizing, capacitor, or transformer breaker is much smaller than that of a bus tie breaker, used as a line breaker, or line breakers. The chances of a fault occurring are therefore less; however, if the fault does occur, it is more likely to approach the maximum calculated value. The probability of a fault occurring on the terminals of a line breaker are remote. Since the breaker duty decreases as the fault-location distance increases from the breaker location, it is logical to apply a probability factor to line breakers especially for ground faults on lines protected by a section of overhead ground wire adjacent to the stations.

Asymmetry of fault current to be interrupted should be considered when the circuit breaker is sensitive to d-c offset, especially for high-speed breakers located near generating stations.[2] The degree of fault-current asymmetry is a function of the phase position of the voltage at the time of fault. If the fault occurs at maximum voltage, there is no offset but if the fault occurs at the zero point of the voltage wave, complete offset results. The offset of the fault current varies within these limits resulting usually in an increase of the symmetrical current values.

For 230-kv 3-cycle oil circuit breakers at Grand Coulée, an offset of approximately 50 per cent should be considered which increases the rms fault current by 22 per cent. Similar breakers away from generating plants can expect a maximum offset of 30 to 40 per cent or less, which is equivalent to a 10 to 15-per-cent increase in fault current.

Conclusions

It is important in the appraisal of circuit-breaker fault-current interrupting duty to use the actual phase current through the breaker. The most severe total fault current will result for a 3-phase fault if the X_0/X_1 ratio is greater than unity. The most severe total fault current will result for a single-phase-to-ground fault if the X_0/X_1 ratio is less than unity and greater than approximately 2/10th. Lower ratios will produce the greatest fault current with a 2-phase-to-ground fault.

All faults with the exception of the phase to phase fault are of equal magnitude if the X_0/X_1 ratio is unity. Other factors to be considered in the determination of the maximum probable fault current to be interrupted are possible fault resistance, possible asymmetry of fault current, and degree of physical exposure of associated circuits to faults.

Bibliography of Relay Literature 1950–1952

ERIC T. B. GROSS
FELLOW AIEE

THIS bibliography is a continuation of similar bibliographies of relay literature which have been published previously and are contained in the following volumes of the *AIEE Transactions:*

1927–1939, vol. 60, 1941, 1435–47.
1940–1943, vol. 63, 1944, 705–09.
1944–1946, vol. 67, pt. I, 1948, 24–27.
1947–1949, vol. 70, pt. I, 1951, 247–50.

The papers listed include those in the field of relaying, as well as in associated fields, published in this country. Included are articles covering relaying, as well as service restoration, testing, system stability, methods of calculation, instrument transformers and other auxiliary devices, which are available in *Science Abstracts, Section B*, and in other digesting or indexing periodicals, as well as in the original magazines listed.

Depending upon the general substance of each article, the listing of the titles is subdivided into 13 sections. The entries in each section are numbered consecutively and listed by year in alphabetical order, the name of the first author determining the alphabetical position. Though some of the papers referred to may cover material in various sections, each title is listed in only one section. A list of periodicals which have been cited and their place of publication is given on page 48.

6. Use of Compensated Selective Impedance Elements for the Detection of Faulty Phases, A. B. Chernin. *Elektrichestvo*, no. 9, 1951, pp. 12–18.

7. The Technical Basis of Resistance Measurement in the New Siemens Line Protection, H. Neugebauer. *Siemens Zeitschrift*, vol. 25, 1951, pp. 244–51.

8. Analysis of the Indications of Distance Impedance Relays on Very Long Lines, S. S. Rafili. *Elektrichestvo*, no. 6, 1951, pp. 51–58.

9. Progress in the Construction of Selective Protective Installations, G. Stark. *Elektrotechnik*, vol. 5, 1951, pp. 407–11.

10. Grapho-Analytical Method of Investigating the Performance of Distance Relays, G. I. Atabekov. *Elektrichestvo*, no. 2, 1952, pp. 23–32.

11. Influence of the Star-Delta Transformation on the Operation of Distance Relays, G. I. Atabekov. *Ibid.*, no. 5, pp. 20–23.

12. Breakdown and Relay Protection, J. L. Braten. *Elektroteknisk Tidsskrift*, vol. 65, 1952, pp. 277–86.

13. Development and Testing of an Experimental System of Discriminating Protection for Faults Between Phases and Phase to Earth on High Voltage Lines and Networks with the Neutral Completely Insulated, A. Parrini, E. Sailer, G. Segre. *Report No. 318* CIGRE, 1952.

14. Double Earth Fault Tests on the Austrian 220 kv System, W. Weller, F. Zimmermann. *Osterreichische Zeitschrift fur Elektrizitaetswirtschaft*, vol. 5, 1952, pp. 75–77.

Section B. Line Protection—Pilot Wire and Carrier Current

1. Line Tuning Equipment Used with Coaxial Cable for Carrier Current Installation on Power Lines, Howard J. Sutton. *AIEE Transactions*, vol. 68, pt. I, 1949, pp. 44–49.

2. Carrier Relaying Aids 115-kv New England Tie Lines, H. L. Goodrich. *Electrical World*, vol. 133, no. 11, Mar. 13, 1950, pp. 84–86.

3. The Intertripping of Remote Circuit Breakers on Electric Power Systems, A. P. Gordon, J. Rushton. *Metropolitan-Vickers Gazette*, vol. 23, 1950, pp. 228–32.

4. Current Transformer Difference Overcome with Percentage Type Relay, J. H. Samson, E. L. Michelson. *Electrical World*, vol. 134, Dec. 8, 1950, pp. 96–98, 111.

5. The Application of Phase-Comparison Principles to Power-Swing Conditions on Long High-Voltage Transmission Lines, G. W. Donaldson. *Proceedings*, Institution of Electrical Engineers, vol. 98, pt. 2, 1951, pp. 47–49.

6. Choice of Telemetering Systems and Channels for a Power System, C. K. Duff. *AIEE Transaction*, vol. 70, pt. I, 1951, pp. 1086–91.

7. Factors in the Choice of Microwave and Carrier Channels for Power System Operation and Dispatching, F. C. Krings. *Proceedings*, Midwest Power Conference, vol. 13, 1951, pp. 351–57.

8. Measurements and Tests on a Power Line Carrier Relaying System, R. H. Miller, A. R. Worthington. *AIEE Transactions*, vol. 70, pt. I, 1951, pp. 1005–07.

9. A New Carrier-Current Frequency-Shift System for Use with Differential Protection of Transformer Banks, R. W. Beckwith. *Ibid.*, pp. 832–35.

10. Considerations in Selecting a Carrier Relaying System, R. C. Cheek, J. L. Blackburn. *AIEE Transactions*, vol. 71, pt. III, Jan. 1952, pp. 10–18.

11. Experimental Investigation of Transient Interference from Power Line Faults on Carrier Current Equipment with Reference to Relaying, H. Elmlund, S. Engstrom, A. Hollner. *Paper 303*, CIGRE, 1952.

12. Power-Line Carrier for Relaying and Joint Usage, Part II. A Survey of Modern Power-Line Carrier Systems, G. W. Hampe, B. W. Storer. *AIEE Transactions*, vol. 71, pt. III, Aug. 1952, pp. 661–70.

13. Protective Relaying Over Microwave Channels, H. W. Lensner. *Ibid.*, Jan., pp. 240–05.

14. Pilot Relaying for Transmission Systems, S. C. Leyland, J. L. Blackburn. *Paper 310*, CIGRE, 1952.

15. A Phase-Comparison Carrier-Current

Paper 55-93, recommended by the AIEE Relays Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 18, 1954.

Eric T. B. Gross is with the Illinois Institute of Technology, Chicago, Ill.

Relaying System for Broader Application, **N. O. Rice, J. S. Smith.** *AIEE Transactions*, vol. 71, pt. III, Jan. 1952, pp. 246–50.

16. The Protection of Teed Feeders, **J. Rushton, F. A. Stary.** *Metropolitan-Vickers Gazette*, vol. 24, 1952, pp. 247–56.

Section C. Line Protection—Ground Faults

1. Earth-Leakage Protection, **C. A. Martin.** *Transactions*, South African Institute of Electrical Engineers, vol. 41, 1950, pp. 133–204.

2. Sensitive Ground Protection, **AIEE Committee Report.** *AIEE Transactions*, vol. 69, pt. I, 1950, pp. 473–76.

3. Operating Experience with Ground Distance Relays, **M. P. Osburn, P. L. Dandeno.** *Ibid.*, vol. 70, pt. II, 1951, pp. 1508–16.

4. Ground Fault Relay Protection of Transmission Lines, **J. L. Blackburn.** *Ibid.*, vol. 71, pt. III, Aug. 1952, pp. 685–92.

5. Ground Relay Polarization, **J. L. Blackburn.** *Ibid.*, Dec., pp. 1088–95.

6. Suitable Current Polarizing Sources for Ground-Type Relays, **O. A. Lentz.** *Electrical World*, vol. 138, Dec. 29, 1952, pp. 74–76.

7. The Adjustment of Earth Fault Protection with Cable Current Transformers, **A. V. Ostrovskaya, I. M. Sirota.** *Elektricheskie Stantsii*, no. 3, 1952, pp. 30–32.

8. Sensitive Earth-Fault Protection with Cable Type Current Transformers, **I. N. Popov.** *Elektrichestvo*, pp. 3, 1952, pp. 38–43.

Section D. Line Protection—General

1. Relaying of Transmission Lines from New Sunbury Generating Station, **H. H. Green, J. A. G. Oewel, O. Ramsaur.** *AIEE Transactions*, vol. 68, pt. II, 1949, pp. 873–78.

2. Relay Protection for Medium Length High-Voltage Transmission Lines, **J. H. Kinghorn.** *Ibid.*, vol. 69, pt. I, 1950, pp. 461–67.

3. Transmission-Line Protection of Short Lines of the Metropolitan Area of a Typical System, **W. E. Marter.** *Ibid.*, pp. 468–72.

4. Unique Protection Required for Midwest Interconnection, **A. J. Nicholson.** *Electric Light and Power*, vol. 28, Nov. 1950, pp. 90–94, 96.

5. Protection of the French Electric Transmission Network, **M. Dietsch.** *Bulletin*, Association des Ingenieurs Electriciens Sortis de l'Institut Electrotechnique Montefiore, vol. 64, 1951, pp. 331–49.

6. Series Capacitors During Faults and Reclosing, **E. L. Harder, J. E. Barkle, R. W. Ferguson.** *AIEE Transactions*, vol. 70, pt. II, 1951, pp. 1627–42.

7. Short-Circuit in Parallel Cable Connections. Current Distribution and Selective Protection, **G. Schulerud.** *Elektroteknisk Tidsskrift*, vol. 64, 1951, pp. 285–95.

8. Short Circuit Protection in High-Voltage Networks, **I. Bach.** *Elektrotechnika*, vol. 45, 1952, pp. 238–50.

9. Back-up Protection in High Voltage Systems, **C. Jean Richard.** *Bulletin*, Association Suisse des Electriciens, vol. 43, 1952, pp. 425–28.

10. Automatic Reclosing on the French Power Transmission System, **L. Roche.** *Bulletin*, Societe Francaise des Electriciens, Series 7, vol. 2, 1952, pp. 501–12.

11. Simple but Foolproof Scheme of Back-Up Cable Relaying, **George Steeb.** *Electrical World*, vol. 137, June 30, 1952, pp. 76–78.

Section E. Bus Protection

Section F. Apparatus Protection

1. Shipshaw Relay Protection, **J. T. Madill, F. H. Duffy.** *AIEE Transaction*, vol. 68, pt. I, 1949, pp. 50–58.

2. Differential Relay Sensitivity Adjuster, **C. L. Headley.** *Ibid.*, vol. 69, pt. II, 1950, pp. 1203–06.

3. Back-up Protection for System Faults at Generator, **D. C. Hoffmann.** *General Electric Review*, vol. 53, no. 2, 1950, pp. 38–41.

4. Theory and Application of Transformer Differential Protection, **George W. McKenna.** *AIEE Transactions*, vol. 69, pt. II, 1950, pp. 1197–1202.

5. Note on the Performance of the Differential Protection of Transformers, **M. Poli.** *Paper 112*, Associazione Elettrotecnica Italiana, vol. 2. 1950, pp. 107–12.

6. A New Carrier-Current Frequency-Shift System for Use with Differential Protection of Transformer Banks, **R. W. Beckwith.** *AIEE Transactions*, vol. 70, pt. I, 1951, pp. 832–35.

7. Thermal Relay for Protection of Transformers on Overload (Westinghouse Type T.R.O. Relay), **H. Demoulin, L. Marique.** *Ateliers de Constructions Electriques de Charleroi*, no. 1, 1951, pp. 18–29.

8. A New Heat Operated Relay for Protection of Transformers, Cables and Other Electrical Machinery, **P. Ignacz.** *Elektrotechnika*, vol. 44, 1951, pp. 308–11.

9. Earth Fault Protection of Generators in Resistance Earthed Networks, **G. Lengyel.** *Ibid.*, pp. 335–44.

10. Instantaneous Balanced Current Protection Using a High Impedance Relay with Bar-Primary Current Transformers, **J. Rushton, F. E. Wellman.** *Metropolitan-Vickers Gazette*, vol. 23, 1951, pp. 369–78.

11. A New Type of Temperature Relay Used for Protection of Transformers, **L. Marton.** *Elektrotechnika*, vol. 44, 1951, pp. 312–19.

12. Protection of Series Condensers Against External Disturbances and Internal Faults, **R. Pelissier.** *Bulletin*, Societe Francaise des Electriciens, series 7, vol. 1, 1951, pp. 492–98.

13. Power Transformer Protection. Checking Connections of "Ratio Differential" and "Circulating Current Relays," **V. B. Shah.** *Electrical Review*, vol. 149, 1951, pp. 937–40.

14. Relay Protection of A-C Generators, **AIEE Committee Report.** *AIEE Transactions*, vol. 70, pt. I, 1951, pp. 275–82.

15. Sensitive Ground Relaying of A-C Generators, **Eric T. B. Gross.** *Ibid.*, vol. 71, pt. III, Apr. 1952, pp. 539–44.

16. Recent Achievements in the Field of Generator Earth Leakage Protection, **R. Kurdziel.** *Przeglad Elektrotechnicsny*, vol. 28, 1952, pp. 190–201.

17. Instrumentation Details of the New Siemens Differential Protection, **H. Neugebauer.** *Siemens Zeitschrift*, vol. 26, 1952, pp. 219–24.

18. Novel Frame Protection for High-Voltage Machines, **H. Steel.** *Deutscher Elektrotechniker*, vol. 6, 1952, pp. 374–76.

19. The Operation of Turbo Alternators Under Unbalanced or Out-of-Step Conditions, **A. Wust, J. Dispaux.** *Paper 106*, CIGRE, 1952.

Section G. Distribution and Network Protection

1. Protection Against Short-Circuits on the 22-kv Network in South Bohemia, **J. Heral, J. Richtr.** *Elektrotechnicky Obzor*, vol. 40, 1951, pp. 372–79.

2. Relay Protection of 33-kv Tie Feeders, **W. H. O'Connor, H. D. Ruger.** *Electrical Engineering*, vol. 71, Feb. 1952, pp. 165.

3. New Selective Protective Circuits for Medium-Voltage Distribution Substations and High-Voltage Transformer Stations, **C. Ramelot.** *Bulletin*, Association des Ingenieurs Electriciens Sortis de l'Institut Electrotechnique Montefiore, vol. 64, 1951, pp. 99–112.

4. Experience with 3-ph. Low-Voltage Interconnected Networks in Berlin, **H. Weber.** *Elektrotechnische Zeitschrift*, vol. 73, 1952, pp. 162–65.

Section H. Service Restoration

1. The Bonneville Power Administration Relaying and Reclosing Program, **Clifford C. Diemond, Donald L. Wylie.** *AIEE Transaction* vol. 69, pt. II, 1950, pp. 1039–48.

2. High-Speed Auto-Reclosing for High-Voltage Transmission Systems, **R. K. Edgley.** *Reyrolle Review*, no. 141, 1950.

3. An Improved Reclosing Relay, **L. E. Goff.** *AIEE Transactions*, vol. 69, pt. II, 1950, pp. 1480–87.

4. Consideration of Requirements and Limitations of Relaying and High-Speed Reclosing on Long and Heavily-Loaded Transmission Lines, **C. E. Parks, W. R. Brownlee.** *Ibid.*, pt. I, pp. 103–09.

5. Combined Application of Automatic Reclosing, a New Protective Relay, and an Arc-Suppression Coil, **B. Pavlovsky.** *Elektrotechnicky Obzor*, vol. 39, 1950, pp. 310–18.

6. The Fault Removal Service of the (Austrian) Interconnected Network, **K. Mayer.** *Osterreichische Zeitschrift fur Elektrizitaetswirtschaft*, vol. 4, 1951, pp. 171–75.

7. Single Pole Reclosing: Relaying Problems and Arc Extinction Times, **W. P. Dobson, V. V. Mason.** *Paper 316*, CIGRE, 1952.

8. Relay Equipment Designed for Automatic Reclosing, **E. Elmlund, T. Holm.** *ASEA Journal*, vol. 25, 1952, pp. 91–102.

9. Experience with Auto-Reclosing Systems on 220 and 150 kv Systems of Electricite de France in 1950 and 1951, **Petard.** *Bulletin*, Societe Francaise des Electriciens, series 7, vol. 2, 1952, pp. 513–15.

10. Relay Protection and Automatic Phase Reclosing on Short Circuit Between Two Phases and Short Circuit of a Phase to Earth, **M. P. Razenknop, A. B. Chernin.** *Elektricheskie Stantsii*, no. 3, 1952, pp. 33–38.

11. Rapid Reclosing Tests on a 30-kv Distribution Network, **B. Thoren.** *ASEA Journal*, vol. 25, 1952, pp. 102–08.

Section I. General and Miscellaneous Relaying

1. New Direct-Acting Relay for Ring-Type Networks, **A. Matena.** *Engineers Digest*, vol. 11, 1950, pp. 347–48.

2. Relaying Practices and Economical Switching Station Arrangements of the Bureau of Reclamation, **W. A. Morgan, R. W. World.** *AIEE Transaction*, vol. 69, pt. II, 1950, pp. 865–71.

3. Relay Maintenance of a Metropolitan Power System, **W. J. Smith.** *Proceedings*, Midwest Power Conference, vol. 12, 1950, pp. 446–50.

4. A Study of Directional Element Connections for Phase Relays, **W. K. Sonnemann.** *AIEE Transactions*, vol. 69, pt. II, 1950, pp. 1438–51.

5. Directional Relay Circuits for Protection Against Phase-to-Phase Faults, **H. Stalder.** *Brown Boveri Review*, vol. 37, 1950, pp. 166–71.

6. Analysis of the Operation of a Directional Induction Relay with Cylindrical Rotor During Transient Processes, **L. A. Gelbukh.** *Elektrichestvo*, no. 2, 1951, pp. 21–24.

7. Tendencies Regarding Machine Protection of Electricite de France. Characteristics of the French Grid and Their Effect on Line Protection, **P. Henriet.** *Bulletin*, Association des Ingenieurs Electriciens Sortis de l'Institut Electrotechnique Montefiore, vol. 64, 1951, pp. 313–30.

8. Protective Gear, **E. H. Hubert.** *Ibid.*, pp. 35–59.

9. Design Features of a Modern Induction-Pattern Overcurrent Relay, **H. S. Lewis.** *General Electric Review*, vol. 18, 1951, pp. 111–23.

10. Protective Relaying on Industrial Power Systems, **Carl M. Lathrop, Charles E. Schleckser.** *AIEE Transaction*, vol. 70, pt. II, 1951, pp. 1341–45.

11. Bibliography of Relay Literature 1947–1949, **AIEE Committee Report.** *Ibid.*, pt. I, pp. 247–50.

12. Induction Type Resistance Relay, **A. M. Bresler.** *Elektrichestvo*, no. 9, 1952, pp. 57–60.

13. Selecting A-C Overcurrent Protective Device Settings for Industrial Plants, **F. P. Brightman.** *AIEE Transactions*, vol. 71, pt. II, Sept. 1952, pp. 203–11.

14. Sub-Station Practice (book), **T. H. Carr.** Chapman and Hall, London, England, 2nd ed., 1952.

15. Reactance Relays Discriminate Between Load-Transfer Currents and Fault Currents on 2,300-Volt Station Service Generator Bus, **G. B. Dodds, W. E. Marter.** *AIEE Transactions*, vol. 71, pt. III, Dec. 1952, pp. 1124–28.

16. The Protection of Electrical Power Systems: A Critical Review of Present-Day Practice and Recent Progress, **H. Leyburn, C. H. W. Lackey.** *Proceedings*, Institution of Electrical Engineers, vol. 99 pt. 2, 1952 pp. 47-66.

17. The Application of Transductors as Relays to Protective Gear, **R. K. Edgley, F. L. Hamilton.** *Ibid.*, pp. 297–313, 344–48.

18. Generalized Distance and Differential Protection and the Corresponding Fault Location Devices, **J. Ilivici.** *Bulletin*, Societe Francaise des Electriciens, series 7, vol. 2, 1952, pp. 447–56.

19. Report of Study Committee on Protection and Relaying, **S. Margoulies.** *Paper 332*, CIGRE, 1952.

20. Report of the International Study Committee on Protection and Relaying, **S. Margoulies.** *Paper 325*, Ibid.

21. Blocking Relay for Improvement of Protection of Long 220 kv Lines, **M. F. Melnikov.** *Elektricheskie Stantsii*, no. 10, 1952, pp. 48–51.

Section J. Testing and Analyzing

1. Detection of Overheated Transmission Line Joints by Means of Bolometer, **J. R. Leslie, J. R. Watt.** *AIEE Transactions*, vol. 68, pt. I, 1949, pp. 64–69.

2. Insulator Flashover Deionization Times as a Factor in Applying High-Speed Reclosing Circuit Breakers, **A. C. Boisseau, B. W. Wyman, W. F. Skeats.** *Ibid.*, pt. II, pp. 1058–67.

3. Fault-Throwing Tests on the 132 kv Grid System Under Normal Working Conditions, **W. Casson, F. H. Birch.** *Proceedings*, Institution of Electrical Engineers, vol. 97, pt. 1, 1950, pp. 279–301.

4. Deionization Time of High-Voltage Fault-Arc Paths, **Everett J. Harrington, E. C. Starr.** *AIEE Transactions*, vol. 68, pt. II, 1949, pp. 997–1004.

5. Fault Location by Pulse Time Modulation, **R. W. Hughes, Nelson Weintraub.** *Electrical Engineering*, vol. 69, Nov. 1950, pp. 1009–11.

6. Measuring Apparatus for Relay Equipment, **B. J. Larsson.** *ASEA Journal*, vol. 23, 1950, pp. 31–36.

7. Transient Fault Locator Proves Out in Operation, **L. R. Spaulding,** *Electrical World*, vol. 133, no. 25, 1950, pp. 110.

8. A Transient Fault Locator for High-Voltage Transmission Lines, **L. R. Spaulding, C. C. Diemond.** *AIEE Transactions*, vol. 68, pt. II, 1949, pp. 1005–12.

9. Relay Testing Practices in a Power Company Serving a Large Area, **V. E. Verrall.** *Proceedings*, Midwest Power Conference, vol. 12, 1950, pp. 451–54.

10. Application of Power Line Outage Monitor, **John F. Atkinson, James D. Cooke.** *AIEE Transactions*, vol. 70, pt. II, 1951, pp. 1292–96.

11. Line Fault Location by Impulses, **C. Beguin.** *Cables et Transmission*, vol. 5, 1951, pp. 315–24.

12. The Role of Field Tests on the Network in the Development of High Voltage Equipment, **M. Laborde.** *Bulletin*, Societe Francaise des Electriciens, series 7, vol. 1, 1951, pp. 157–76.

13. Traveling Wave Relations Applicable to Power-System Fault Locators, **Laurel J. Lewis.** *AIEE Transactions*, vol. 70, pt. II, 1951, pp. 1671–80.

14., Impulse Method of Locating Cable Faults, **A. Ya. Usikov, I. Kh. Vakser.** *Elektrichestvo*, no. 10, 1951, pp. 20–23.

15. The Location of Transient Faults on Overhead Lines by Means of Apparatus Measuring the Turning of a Relay Movement. Principles and Results of Operation, **P. Devilane.** *Bulletin*, Societe Francaise des Electriciens, series 7, vol. 2, 1952, pp. 271–80.

16. Turning Relay Apparatus Used for the Location of Transient Faults, **C. Kaplan.** *Ibid.*, pp. 281–87.

Section K. System Stability

1. Stability Conditions of the Swedish Trunk-Line System, **S. Lalander, D. Jungnell.** *Svenska Vattenkraft Foreningens Publikationer*, no. 418, vol. 10, 1950, pp. 343–84.

2. High-Speed Reclosure of Circuit-Breakers, **J. R. Mortlock.** *BTH Activities*, vol. 21, 1950, pp. 188–92.

3. An Electric Analogue Method for the Direct Determination of Power System Stability Swing Curves, **W. B. Boast, J. D. Rector.** *AIEE Transactions*, vol. 70, pt. II, 1951, pp. 1833–36.

4. Methods of Assessing the Stability of an A-C Power System, **R. F. Linsell.** *Engineer*, vol. 192, 1951, pp. 332–34.

5. The Behaviour of Selective Protective Equipment During Phase Swing, **A. Thewalt.** *Elektrotechnische Zeitschrift*, vol. 72, 1951, pp. 20–23.

6. Accurate Computation of 2-Machine Stability, **Ralph D. Goodrich, Jr.** *AIEE Transactions*, vol. 71, pt. III, Aug. 1952, pp. 577–81.

7. Power System Stability Criteria for Design, **W. A. Morgan.** *Ibid.*, Jan., pp. 499–504.

8. A Note on the Equal Area Stability Criterion, **J. E. Parton.** *Proceedings*, Institution of Electrical Engineers, vol. 99, pt. 4, 1952, pp. 204–16.

9. Report of the International Study Committee No. 13: System Stability and Voltage-Load-Frequency Control, **B. G. Rathsman.** *Report 336*, CIGRE, 1952.

10. Comparison, Based on Stability Angle, of Different Types of Reclosing on Transmission Lines and Inter-Connectors, **R. Robert.** *Bulletin*, Societe Francaise des Electriciens, series 7, vol. 2, 1952, pp. 516–25.

Section L. Methods of Calculation

1. Hochspannung und Hochleistung (book), **J. Biermanns.** Carl Hanser Verlag, Munich, Germany, 1949.

2. Calculation of Short-Circuit Currents at Electrically Remote Locations, **R. T. Lythall.** *Iron and Coal Trades Review*, vol. 159, 1949, pp. 1291–94.

3. How to Calculate Relay Settings in Field, **C. L. Betts, Jr.** *Electrical World*, vol. 134, July 31, 1950, pp. 96–97.

4. Handling Power System Problems on an A-C Network Calculator, **P. O. Bobo.** *Electrical Engineering*, vol. 69, Oct. 1950, pp. 867–69.

5. Construction of Short Circuit Current Decrement Curves, **F. P. Brightman.** *Power and Works Engineer*, vol. 54, no. 7, July 1950, pp. 66–69, 118.

6. Analysis of Synchronous Machine Short Circuits, **Robert D. Camburn, Eric T. B. Gross.** *AIEE Transactions*, vol. 69, pt. II, 1950, pp. 671–79.

7. The Calculation of Currents Due to Faults Between Turns in Transformer Windings, **B. L. Coleman.** *Report*, British Electrical and Allied Industries Research Association, ref. Q/T121, 1950.

8. Construction and Operation of Austrian Network Analyzer, **W. Erbacher.** *Osterreichische Zeitschrift fur Elektrizitaetswirtschaft*, vol. 3, 1950, pp. 357–61.

9. Some Experience with a British A.C. Network Analyzer, **G. Lyon.** *Proceedings*, Institution of Electrical Engineers, vol. 97, pt. 2, Dec. 1950, pp. 697–724.

10. New Aid to Network Calculator Operation, **G. P. Wilson.** *Electric Light and Power*, vol. 28, no. 1, 1950, pp. 78–79, 120–21.

11. Network Analyzer for Electric Power Systems. *Engineering*, vol. 169, no. 4381, 1950, pp. 94–95.

12. Analysis of Subsequent Faults, **Howard K. Amchin, Eric T. B. Gross.** *AIEE Transactions*, vol. 70, pt. II, 1951, pp. 1817–23.

13. Short Circuit Power in Auxiliary Circuits of Thermal Power Stations, **H. DeMarsac.** *General Electric Review*, vol. 60, 1951, pp. 5–13.

14. Power Flow in an Interconnected System with Particular Reference to a Special Network Analyzer for Solving Related Problems, **M. R. Dunster.** *Journal*, Institution of Engineers of Australia, vol. 23, 1951, pp. 37–46.

15. The Network Analyzer as an Auxiliary of the Chief Load Dispatcher, **W. Erbacher.** *Osterreichische Zeitschrift fur Elektrizitaetswirtschaft*, vol. 4, 1951, pp. 170–71.

Turbine Generator Operation and Maintenance Practice of Philadelphia Electric Company

E. I. GALLAGHER
ASSOCIATE MEMBER AIEE

THIS paper shows the practice in a typical large power system and is one of a group of papers requested by the Committee on Rotating Machinery, Synchronous Machinery Subcommittee, in connection with their work in preparing a proposed AIEE guide for the operation and maintenance of turbine generators. It is presented primarily for the purpose of focusing attention on this subject and of stimulating discussion of any points involving a difference of opinion or practice.

Description of System

The Philadelphia Electric Company system includes seven steam and one hydro generating stations with a total installed capacity of 2,286 megawatts (mw). The Company is a member of the Pennsylvania-New Jersey Interconnection which operates installed capacity of 7,756 mw. The Company's generating capacity by steam is distributed among 32 units, ranging in size from 14 to 182 mw. Seven of these generators exceed 100 mw capacity. Generator voltages are all at 13,800 volts except the latest addition which is 20,000 volts.

The 1953 system peak was 1873 mw with 978 megavars (mvar). There are five synchronous condensers of 30 mvar each and approximately 50 mvar of fixed static condensers on the system. An additional 75 mvar are available on the 60-cycle motors of the frequency converters which supply the railway and streetcar load. The system power factor varies from 84 per cent at heavy-load periods to 91 per cent during light-load periods.

Scheduling of Load

The units are loaded on an incremental cost basis. This means that only those

Paper 55-117, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 21, 1954; made available for printing November 24, 1954.

E. I. Gallagher is with the Philadelphia Electric Company, Philadelphia, Pa.

units required for generation and local area or interconnection reserve are in service. All other units are taken off the line as load conditions permit. As a result, about nine machines are put on the line every morning. Some units may be put on twice a day for short periods over the peaks. Others have a 24-hour demand and are taken off only when necessary. One unit operated continuously for over 6 months and was taken off at the manufacturer's recommendation to test the overspeed trip mechanism.

Reactive is adjusted on the generators, converters, and synchronous condensers to attain the best conditions. Generators are never operated with leading power factor; as far as possible the reactive is carried in the area where it is required. This reduces transmission line loading and losses. The maximum loading of the generator is limited by the name-plate rating for field or armature current, or maximum permissible coil temperature. None of these values is ever exceeded. Normally, the maximum loading is determined by the field or armature current. Maximum coil temperatures run up to 90 degrees centigrade (C) on some generators at full load. However, the maximum on most generators is about 70 C.

Operation of Units

The system is operated on 13- and 33-kv bus voltage schedules for the various locations. The generators carry the required voltage to maintain the scheduled bus voltage and the necessary reactive. In accomplishing this the generator terminal voltage may be 5 per cent over the rated voltage for the machine.

Voltage regulators are used on nearly all the generators. Rheostatic and the vibrating type of regulators control voltage on the older generators while the static type with fast response control voltage on the newer large generators. They have been very satisfactory. The regulators are cleaned and inspected on a routine schedule. The larger units are provided with a minimum excitation limit to prevent instability.

The fundamental generator protection is a current differential relay on the windings. Some of the generators have phase and ground overcurrent relays for back-up protection. Several units have reverse power relays which are primarily for turbine protection. On loss of field the procedure is to trip the unit immediately. Loss of field relays are being installed on the larger units.

Condensing units from 60 to 182 mw capacity are taken off nightly for as short a time as 4 hours. These units are returned to service in 20 minutes after shutdown of less than 8 hours. The limiting factor in the rate of loading the unit is the turbine conditions. The generator is not considered. Generally, units going on the line are loaded at a rate of not more than two per cent per minute of the full load rating. After they are on the line, and operating conditions are normal, larger rates of change are made. Preheating of the field in starting has been used for three large units on recommendation of the manufacturer.

Cooling of Generators

The cooling systems of air-cooled generators are operated to maintain substantially constant coil temperatures. Cooling water is adjusted manually to accomplish this. Several air-cooled systems have electric heaters in the air ducts to maintain a temperature high enough to prevent condensation while the unit is off the line. This also helps to maintain constant coil temperature.

Hydrogen-cooled generators maintain a constant ambient. This is done by holding the cold gas temperature constant, usually at about 35 C. Control is by manual adjustment of the cooling water.

The hydrogen pressure carried on any particular unit depends upon the load dispatcher's requirements for reactive. The generating station is informed of the estimated kva required from the unit, and sufficient hydrogen pressure is maintained to carry the estimated load on the generator. This procedure reduces hydrogen consumption and leakage. Normally the maximum kva required from a generator will not vary much from day to day on units capable of operating at 15 pounds per square inch gauge or higher hydrogen pressure. These, being the newer and more efficient units, will carry full load daily. In the event that more reactive is required, the hydrogen pressure can be quickly increased.

At present, there has been no occasion to operate above 15 pounds per square inch gauge hydrogen pressure except for generator capability tests. At 15-pounds-per-square-inch gauge, hydrogen leakage may amount to 250 cubic feet per day on large generators. Hydrogen consumption is watched closely and any increase is noticed immediately. Leakage is checked with an explosimeter type of detector.

Maintenance of Generators

Generator maintenance may be divided into electrical and mechanical phases. The maintenance section inspects for physical damage to the generators. They look for loose wedges, broken supports, core movement, coil distortion, tape separation, loose retainer rings, and any other visible defect. Collector rings are never ground or polished unless they are giving trouble. Nothing is done to them on the basis of appearance. Generator fields on closed cooling systems are not removed at every inspection period.

The field-winding resistance is carefully measured during complete inspections. Variations from the original value are carefully noted and any appreciable change is investigated. This has shown up loose connections in the field leads of several machines.

The station forces megger the armature and field at 500 volts every month or when possible. No routine high-voltage tests are made except when there is suspected damage or repairs or replacements in the electrical circuit. At present, several generators have difficulty with tape separation and they are given a hi-pot annually. Absorption tests are made for 10 minutes during each complete inspection period, in general with the use of 500 volts for the field, and 1,000 and 10,000 volts for the armature.

Conclusions

Since internal inspections after the first year have shown relatively little trouble, the period between complete inspections is being extended to as much as 5 years. No generator-forced outages have been attributed to operating practices.

An Anechoic Chamber for Noise Tests on Large Power Transformers

A. W. BENOIT
NONMEMBER AIEE

R. T. HEMMES
MEMBER AIEE

M. W. SCHULZ, JR.
ASSOCIATE MEMBER AIEE

THE completion in 1954 of the world's largest anechoic chamber as part of General Electric's transformer sound laboratory focussed attention on the efforts being made to reduce transformer noise. The noise produced by transformers, while not a new problem, has become increasingly important with the rapid growth of the electric power industry and the expansion of residential districts. The advantages of the unit substation and other economic factors have brought about a trend toward the installation of more, and in many cases larger, transformers in residential areas. The resulting noise complaints have made it evident that noise must be given special consideration in the design of a transformer installation. For many applications transformers with noise levels considerably below the National Electrical Manufacturers' Association (NEMA)[1] standard limits are required.

The use of cold-rolled core steel with its improved loss characteristics has permitted manufacturers to produce smaller, lighter, and less costly transformers to meet given electrical specifications, but in many cases this has caused the noise level to be higher than that of earlier units built of hot-rolled steel. It is now recognized that noise level may be a limiting design criterion.

None of the methods presently available to the transformer design engineer for reducing noise level are particularly effective when measured in terms of incremental cost per decibel (db). A 10-per-cent reduction in operating flux density in the core, e.g., results in only about 3 db reduction in noise level, but it represents an appreciable increase in cost.

Thus two factors, (1) the need for special attention to noise because of the nature of the ultimate environment of the transformer, and (2) the emergence of noise level as a critical design specification, have led both users and manufacturers of power transformers to devote considerable time and effort to the investigation of the transformer noise problem.

This paper describes some of the details of the design, construction, and operation of the first anechoic chamber built for noise testing large power transformers. It is shown how the acoustic treatment of the test area and new developments in instrumentation contribute to unprecedented accuracy in the measurement of transformer noise. Better data will provide a more complete understanding of the problem and lead to new methods for its solution.

Facilities Required

One of the main difficulties facing the manufacturer in the investigation of noise problems is the procurement of accurate data which are independent of the particular surroundings in which the measurements are made. For convenience, the sound testing activities may be divided into two categories, acceptance testing and development work.

ACCEPTANCE TESTING

The well-known NEMA standards for transformer noise are the basis of all acceptance tests although the standard limits are often modified in accordance with customer specifications. It has long been recognized that the NEMA standards are far from ideal, but they do represent a means for obtaining reasonable estimates of noise performance with a minimum of special facilities.

There are two important requirements which must be fulfilled by the space in which noise measurements are made if accuracy is to be obtained. First, the ambient noise must be low enough to keep it from contributing appreciably to the readings, and second, the reflection of sound from walls or near-by objects must be controlled to prevent excessive errors.

The NEMA standards recognize the second requirement by stating that all reflecting surfaces should be 10 feet or more from the transformer. This requirement can be satisfied by clearing a space on the factory floor; however, the noise of numerous other sources, such as transformers in the vicinity undergoing electrical test, generators supplying power to the test area, and overhead cranes, produce an ambient noise level much too high to allow satisfactory noise testing. Therefore the only alternatives are (1) to make the tests at a time when these other noise producing activities have been suspended, (2) to provide a special acoustically treated room, or (3) to make the tests at some remote outdoor site. The first two methods have been used at Pittsfield. Units up to 5,000 kva were tested in a small "noise room." The larger units were tested on the floor of the factory on week ends or holidays and required special scheduling

DEVELOPMENT WORK

Tests must be performed to provide information for transformer design engineers to enable them to calculate noise levels, to evaluate changes in the design or the manufacturing process, to determine, the physical laws governing the generation, transmission, and radiation of transformer noise, and to determine the reaction of people to noise. Frequently a variety of dynamically scaled models of transformers and associated structures such as barriers require study. The experiments usually require special measurements such as frequency analyses. The greatest possible accuracy is necessary so that small changes which may be quite important can be evaluated with a minimum number of samples.

The accuracy of a sound level reading in the presence of reflecting objects is greatly affected by the distance between the microphone and the sound source; the standard deviation increases quite rapidly with the distance. It is highly desirable in many instances to measure the sound level as a function of space but this cannot be done with uniform accuracy in a room with reflecting surfaces. For developmental purposes it is highly desirable to have available a special room with low ambient sound level, free from reflections, and providing a large working space. These needs, coupled with those for acceptance testing large power transformers on a more orderly schedule, led to the decision to build an anechoic (without

Paper 55-26, recommended by the AIEE Transformers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 25, 1954; made available for printing November 15, 1954.

A. W. BENOIT (retired) was with Charles T. Main, Inc., Boston, Mass., and R. T. HEMMES and M. W. SCHULZ, JR., are with the General Electric Company, Pittsfield, Mass.

The outstanding work of Briggs Gettys in the preparation of general specifications for the sound laboratory was largely responsible for its creation. The detailed acoustical design of the anechoic chamber was prepared by the consulting firm of Bolt, Beranek and Newman, Inc., and the structural design was by Charles T. Main, Inc. The Gilbane Building Company was the general contractor. The authors regret that it is impossible to enumerate the contributions of the many persons who have been associated with the design, construction, evaluation, and operation of the sound laboratory.

Fig. 1. Exterior view of sound laboratory

echo) chamber which could accommodate the largest transformers now anticipated.

Sound Test Laboratory

A study of the trends in transformer development and other forcasts of future sound testing requirements resulted in specifications for a noise test building.

SPECIFICATIONS

It appears reasonable to expect that transformers weighing 400 tons and measuring more than 37 feet by 27 feet and 33 feet high will be built and will require noise tests. Such units may have a rating in excess of 500,000 kva. The noise test chamber must be large enough to provide safe electrical clearance from the bushings of the largest transformer and also to allow accurate sound level readings to be taken at least 6 feet from the string contour of the transformer.

It is necessary that the ambient sound level be less than 40 db on 40-db weighting. A level of less than 30 db is desirable. To simulate tests on the open ground a hard floor and reflection-free walls and ceiling are necessary. For other tests it is desirable to approach anechoic conditions.

The sound level meters and other instruments should be the most stable and accurate permitted by the state of the art. Facilities must be provided for easily checking and calibrating the instruments.

GENERAL DESCRIPTION

The sound laboratory depicted in Fig. 1, built at a cost of approximately $1,500,000 meets all of the specifications just given. As shown in Fig. 2, it consists of four major sections: the entrance chamber, the anechoic chamber, the control and storage rooms, and the auxiliary transformer rooms.

Normally a fully assembled transformer is placed on a special transfer car and transported on standard gauge rails through the entrance chamber into the anechoic chamber. The entrance chamber provides a working space and temporary storage for equipment awaiting test. The transformers to be tested can be brought into this chamber and the outer door closed before the door to the test chamber is opened. Thus the anechoic chamber is protected from adverse weather conditions. Forced-air heat exchangers in the entrance chamber are used for heating the anechoic chamber when the intervening doors are opened.

The anechoic chamber is a reinforced concrete building with all structural supporting members of the walls and roof on the outside. This provides a room 66 feet long, 56 feet wide, and 50 feet high with smooth unobstructed interior surfaces. The actual working area, after the acoustic treatment has been added, is about 7 feet less than these dimensions. The transformer and transfer car are supported by rails which rest on a massive concrete foundation which has been designed to allow maximum coverage by acoustic absorbing materials. Fig. 3 shows the interior of the anechoic chamber.

There are two consoles of instruments in the control room. One contains the sound measuring instruments and the other the controls for the power circuits which supply the excitation to the transformer being tested. There is an observation window next to each of the consoles so that the operators may view activities in the anechoic chamber.

The auxiliary transformer rooms contain the step-up transformers which are used to supply power to the transformer being tested, the circuit breakers, potential and current transformers, and other auxiliary power sources.

ANECHOIC CHAMBER

To provide a low ambient sound level and high absorption coefficient, the walls, floor, and ceiling are massive, multilayer structures covered with sound absorbing material. The doors are similar and have special hardware and gaskets to seal them. Fig. 4 shows a cross section of the walls. They consist of 12-inch reinforced concrete, 2-inch Fiberglas, 8-inch solid concrete blocks, 0.030-inch copper sheet, 6-inch air space, and 28-inch Fiberglas wedges. The concrete block wall is tied to the 12-inch wall by resilient connectors. The floor and roof are very similar except that the concrete blocks are replaced by 6-inch reinforced concrete slabs and minor changes are necessary in the method of supporting the structures.

The copper sheet provides radio-frequency shielding so that measurements may be made of the radio and television interference caused by transformers. The shield is continuous with all joints interlocked, rolled flat, and soldered. The copper sheet is omitted from the steel doors but continuous electric ground connections are provided. Even the observation windows are covered with fine mesh copper screens. All power lines entering the anechoic chamber have radio-frequency filters. Lighting fixtures are incandescent, not fluorescent, and all

G—28-inch Fiberglas wedges

metal parts of the acoustical treatment are grounded.

A notable feature of the building is the main door, made up of two leaves covering an opening 30 feet wide by 37 feet high. Since each leaf of the door weighs about 30 tons a sliding door was considered more practical than a hinged suspension. Each leaf is carried on power-driven wheels operating on rails. The doors consist of two 4-inch thick compartments constructed of structural steel channels and 1/4-inch thick steel plates. The outer compartment is filled with dry sand and the other is filled with Fiberglas. The seal around the door frame consists of a rubber tube which can be inflated with compressed air and a strip of foam rubber forms the seal between the two leaves of the door when they are closed.

The observation windows between the control room and anechoic chamber consist of two wood frames, one set in the 12-inch concrete wall and the other in the 8-inch concrete block wall. A 1/2-inch thick plate glass and a 3/8-inch thick plate glass are set in the first frame about 8 inches apart but not parallel to each other. In the other frame is a 5/16-inch thick plate glass. This construction is similar to that used in radio studios and greatly attenuates any sound transmitted through it.

To approach anechoic conditions, all surfaces of the room must have acoustic absorption coefficients of 0.99 or better at the frequencies of interest. This means that less than 1 per cent of the sound energy striking the surface is reflected. Fiberglas wedges are the most practical treatment which will provide this degree of absorption at a frequency of 120 cycles per second (cps), which is the fundamental noise component of most transformers.[2–4]

The wedges are installed on all the walls, the floor, and the ceiling of the anechoic chamber and cover these surfaces as completely as possible. The main doors have wedges installed on them and portable wedges are available to cover the tracks in the center of the room. Part of the door frame and the small personnel doors are covered by a Fiberglas blanket. The only surfaces which have not been treated with absorbing materials are the two observation windows and several junction boxes which contain outlets for microphone cables and auxiliary power circuits but they have a negligible effect on the acoustic quality of the room because of their relatively small size.

The working floor to support the operators and small test equipment consists of 3/32-inch galvanized stranded aircraft cable interwoven on 2-inch centers each way. The cables are individually spring-supported and are normally under a tension of 450 pounds. The floor is usually 10 inches above the tips of the wedges but may sag as much as 6 inches when supporting small groups of people. This floor does not impair the anechoic quality of the room.

To simulate the condition of a transformer installed on a reflecting surface, such as a hard floor or the ground, a removable plywood floor has been provided. This floor is supported just above the wire floor by a pipe and angle frame and is entirely independent of the spring floor.

TRANSFER CAR

For normal acceptance testing a transformer is completely assembled, filled with oil, loaded on the transfer car, and moved into position in the anechoic chamber. The transfer car has been specially designed to carry 400 tons and to support the transformer during the test. This eliminates the need for crane facilities in the anechoic chamber but it does require that the transfer car provide a dynamically rigid support, particularly at 120 cps.

Hydraulic jacks which have been built into the car bear on the rails and lift the car about $1^{1}/_{2}$ inches. Aluminum shims are placed between the car frame and the concrete foundation so that when the car is lowered it rests on a solid support. The frame of the car is a rigid structure and has been designed so that it has no modes of vibration in resonance near 120 cps.

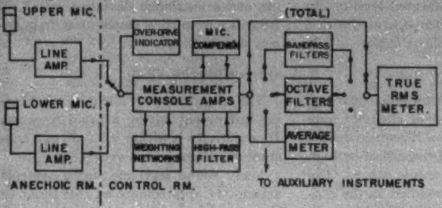

Fig. 5. Block diagram of instrumentation serving one side of anechoic chamber

Power Supply

The NEMA standards specify that transformers must be excited at rated voltage and frequency with no load applied for noise tests. It is expected that units even larger than 500,000 kva will require noise tests, hence a 12,000-kva 3-phase, 60-cycle generator has been provided to assure good voltage wave form.

A 10,000-kva bank of single-phase transformers in the auxiliary transformer room step the voltage up to the required level. They are 3-winding transformers with series-multiple arrangements for the high-voltage and intermediate-voltage windings. With suitable tap and winding connections and control of the generator voltage it is possible to provide any voltage up to 69 kv.

The generator is controlled by amplidynes which hold the voltages and frequency to better than 0.1 per cent of the values set by the operator. Instruments and appropriate instrument transformers are provided to allow the operator to read the voltage, current, and frequency of the excitation at any time.

Auxiliary power is available in the anechoic chamber to operate fans, oil pumps, or other equipment. Three-phase 60-cycle power from 92 to 503 volts is obtained an autotransformer and induction voltage regulator. A motor-generator set supplies up to 250 volts d-c.

Instrumentation

Given a test chamber of adequate quality, the burden of minimizing tolerances in sound level measurements falls upon the instrumentation. As previously shown, tests on completed large power transformers and development tests pertaining thereto both place a high premium on each db of measured level; a corresponding economic outlay for high accuracy in the measuring equipment is warranted.

The design of the measurement console must provide for high stability and convenient standardization so that in service complete reliance can be placed on each set of readings taken. Consideration must also be given to the need for obtaining large numbers of readings rapidly, since measurements may involve as many as 40 microphone positions around a transformer, with frequency analyses at many positions and possible repetitions of all measurements at several levels of excitation voltage.

Measuring Equipment Layout

Fig. 5 shows in block diagram form the layout of the basic measuring system. There are two such systems, which operate from the north and south sides of the anechoic chamber simultaneously and independently.

The two microphones shown in Fig. 5 are mounted on a single boom, Fig. 6, which automatically maintains one microphone directly above the other. The separation between microphones is made one-third of the tank height of the transformer under test. White cloth tapes are drawn taut around the outer limits of the transformer radiators to show the contour at one-third and two-thirds tank height. The wheeled tripodal stands supporting the microphone booms are then rolled toward the transformer until there is a visual 1/2-inch clearance between the contour tapes and the horizontal rings of $11^{1}/_{2}$-inch radius which surround each microphone, thus assuring the microphone distance of 1 foot specified by NEMA.[1]

The microphones feed into separate line amplifiers in the anechoic chamber. The amplified outputs are fed into the main measurement console in the control room; see Fig. 7. The right-hand panel at center height serves the north side of the anechoic chamber and provides controls for switching in either of the microphones and obtaining sound level measurements at the desired weighting, usually

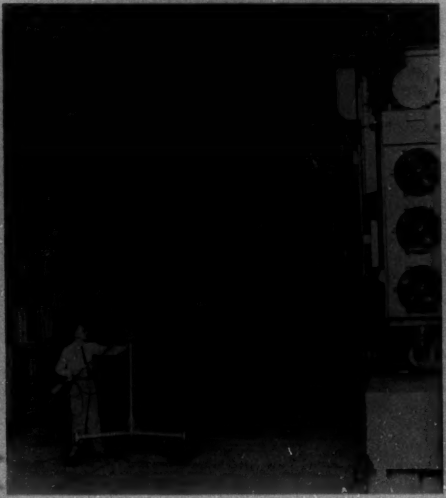

Fig. 6 (left). Microphones and supporting boom

Fig. 7 (below). Console of sound measuring instruments

40-db. Corresponding equipment at the left side of the console serves the south side of the anechoic chamber.

For rapid routine frequency analyses, a band-pass filter set is provided below the sound level measuring panels, which can be switched in to pass 120 cps and successive harmonics thereof individually as a dial switch is advanced. A standard octave band filter set, above the measurements panel, is also provided since octave band information is of increasing interest in transformer noise measurements. The output meter for indicating sound levels is a rapid-acting true rms instrument, inherently more accurate in showing the rms value of highly peaked waves than the instruments found in conventional sound level meters, as will be explained later.

It is recognized that comparative measurements will sometimes be made on transformers after installation in the field, using conventional sound level meters. To delineate the possible extent of measurement error due to waveform considerations, a true average meter has been supplied in the measurement berth. Readings from this meter are for reference purposes only, the official measured level being that supplied by the rms meter.

Thus rapidity of measurement is achieved by the use of four microphones placed semiautomatically, rapid switching, and quick-acting output meters. The end result is that two test operators are kept continuously occupied at the measurement console, recording the levels of total noise and components thereof throughout the test period.

Although rapid measurements are desirable, high accuracy is the paramount interest. Whereas an accuracy in absolute sound pressure measurements of ±2.0 db serves satisfactorily in many industrial applications, an over-all accuracy of ±0.5 db is demanded here. This in turn requires a still smaller tolerance in each of the components of the measuring system, now to be described.

MICROPHONES

Western Electric *640AA* condenser microphones were selected for all routine work in the anechoic chamber. Largely employed in industry as laboratory standards, these microphones are characterized by high stability. For example, a temperature change at the microphone from 25 to 35 degrees centigrade produces a change in sensitivity of approximately 0.1 db. The same temperature change in the case of the crystal microphone supplied with conventional sound level meters causes a change in indicated level of approximately 2.4 db, when operated with a typical 25-foot microphone cable.

AMPLIFIERS

The microphone preamplifiers and line amplifiers in the anechoic chamber were designed by the Western Electroacoustical Laboratory and are distinguished by high stability and large dynamic range. The measurement berth amplifiers in the control room were designed by the Measurements Unit of the Pittsfield High Voltage Laboratory to have high stability and very low distortion. The frequency response is within 0.1 db of being flat from 80 to 8,000 cps. All amplifiers are a-c powered and free from the effects of ordinary changes in line voltage. To remove all possibility of instability from line voltage surges, a separate generator has been provided to supply the instruments.

A thyratron guardian circuit is applied to the line amplifier to signal the test operator if the amplifier saturation level is approached during any part of the signal cycle. In the comparatively rare case where this may occur an insertion loss of 20 db is inserted at the microphone preamplifier and readings are corrected accordingly.

NETWORKS

In accordance with standard practice, three weighting networks are provided, which discriminate against high and low frequency in a manner similar to the human hearing mechanism at three levels of prevailing sound. By selection of the proper network the indicated sound level is made more nearly representative of the sensation of loudness at the ear.

The flat, 70-db, and 40-db weighting networks have been adjusted to offer an identical insertion loss at 1,000 cps and a tolerance of ±0.3 db from the American Standards Association (ASA) design objective[5] over the important frequency range from 120 to 1,200 cps. This tolerance may be contrasted with the ±2.0 to 3.0 db deviation permitted in conventional sound level meters of the same range by ASA standards.

Over the range 80 to 8,000 cps the tolerance of the amplifiers and weighting networks has also been held to ±0.3 db, based on a nondirective microphone. A separate compensating circuit has been included to apply a free-field correction for the *640AA* microphone at high frequencies, with a maximum deviation in the range 1,000 to 5,000 cps of 0.3 db from the computed correction curve. A high-pass filter is optionally available with a cutoff frequency slightly below 120 cps and a maximum deviation of 0.3 db from flat frequency response at frequencies above 120 cps.

OUTPUT METER

The output meter is a true rms indicating instrument having a rapid response. Its sensitivity is within ±0.2 db of a constant value from 80 to over 4,000 cps.

Many sound level measuring systems attempt to approximate an rms response by operating an inherently average-reading instrument on the curved characteristic of a driving circuit. The circuit may have the form of a copper oxide rectifier or a specially biased vacuum tube. A major shortcoming has been the instability of the reference characteristic with change in temperature, polarizing voltage, and age. This situation is reflected in the ASA specifications which permit an error of ±0.5 db in the rms addition of two equal voltages in nonharmonic relation. The superiority of the use of an inherently true rms meter with suitable frequency-compensating network is indicated by a maximum observed error of only 0.1 db when making this test at various points on the instrument scale.

A second consideration is the ability of the instrument to give an rms response to highly peaked waves. In this regard, ASA specifies two tests, the more severe of which requires (after inserting a constant loss between the meter terminals and driving circuit) that two voltages, each initially capable of causing full-scale deflection, be first doubled and then simultaneously applied. The permitted deviation from rms addition in conventional sound level meters is ±1.5 db. The measured error in the equivalent test on the true rms system is 0.3 db. This ability of the instrument to handle peaked waves is important in power transformer measurements, where, with fans inoperative, the noise is concentrated at discrete frequencies in harmonic relation.

FILTER SETS

The electronic band-pass filter sets for rapid routine frequency analyses were custom built by the Western Electroacoustical Laboratory to provide an attenuation of 25 to 40 db to neighboring harmonics while passing individual harmonics of 120 cps up to the sixth. At the same time, each passband is maintained within 0.5 db of flat for a frequency range of at least ±7 per cent from the center frequency. This permits checking transformers for any troublesome resonances of parts by varying the electric excitation frequency from 56 to 64 cps and identifying the offending har-

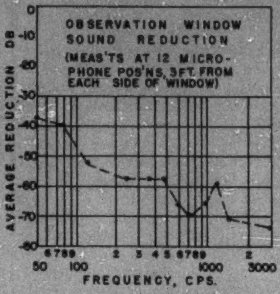

Fig. 8. Sound attenuation of observation window versus frequency

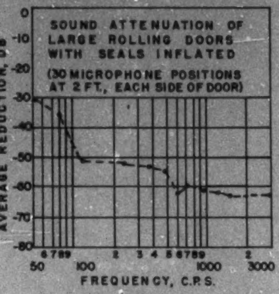

Fig. 9. Sound attenuation of main doors versus frequency

monic of noise. The octave filter sets are of standard manufacture, conforming to ASA specifications.[6]

SYSTEM CHECKS AND STANDARDIZATION

It is imperative that dependable measurements always be obtained on the first attempt. The steps taken in design to insure stability have already been outlined. There remains a possibility in an electronic system of a component failure, causing an error of several db.

To insure that such a condition would be detected during tests, means are provided in the measurement console for the routine injection of an electric signal of known strength into the microphone channel prior to every series of measurements. A resulting normal indication certifies the correct gain in the amplifying and measuring system. Similarly an acoustic check is provided daily or whenever desired by means of a small hood enclosing a calibrated loudspeaker which is slipped over each microphone in turn. While not regarded as a standard, the hood detects any change in microphone sensitivity in excess of 0.5 db.

All microphones receive accurate calibrations under anechoic conditions monthly against the Pittsfield Works Standard, another *640AA* microphone set aside for the purpose. This is compared semiannually with the General Electric Standard at Schenectady and cross checks are made with leading sound laboratories.

AUXILIARY INSTRUMENTATION

A complement of accessory equipment has been provided to cover such nonroutine measurements as may be required of the anechoic chamber. Among the items included are: crystal microphone channels for measurements at very low levels or in applications where microphones must be considered expendable; a 2,500-watt audio amplifier for core vibration studies and other purposes; a moving strip camera and oscilloscope for transient noise studies; a Bruel and Kjaer spectrometer-recorder, and other instruments for general noise analysis work.

Evaluation of Anechoic Chamber

To evaluate the effectiveness of the design of the room, extensive measurements have been made to indicate the degrees of isolation and absorptivity achieved. While much data remain to be analyzed, results can be presented with reference to several salient matters.

ISOLATION

The ambient noise level in the test room is approximately 19 db at 40-db weighting and 42 db without weighting. The effectiveness of the observation windows in providing isolation is shown by the curves of Fig. 8. It will be observed that over the frequency range from 120 to 3,000 cps the difference in average sound levels at a 3-foot distance from the two sides of the window is in excess of 52 db. The curve of Fig. 9 shows the minimum attenuation provided by the large rolling doors at the chamber entrance, with gasket seals inflated.

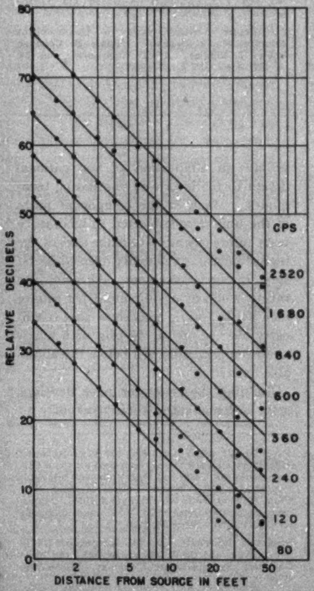

Fig. 10 (left). Comparison of measured sound level to inverse square law, Pittsfield anechoic chamber. Microphone and point sound source 20 feet above centerline of transfer tracks

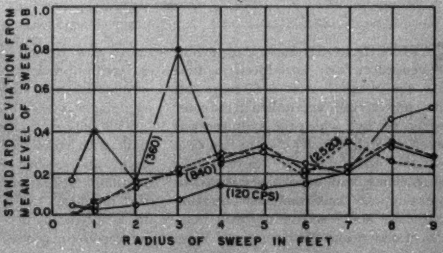

Fig. 11 (right). Variation of sound level at microphone traveling in a horizontal circular orbit about point sound source. Source 8 feet above transfer tracks at center of room. Tracks covered by portable wedges

ABSORPTION

The proximity to a true anechoic condition is indicated by the nearness of the measured curve of sound intensity versus distance to inverse square law; a point source of sound is employed. Fig. 10 shows such data taken with source and microphone on a line 20 feet above the center line of the railroad track within the chamber. The maximum measurement error involved in these data is estimated at ±0.3 db of sound level and ±1 per cent of distance. It will be noted that in the critical range from 120 to 840 cps the minimum distance at which 1 db of deviation occurs is in excess of 16 feet.

In contrast with anechoic chambers previously constructed, the purposes of this room require that it have a railroad track with massive concrete supports, extending for nearly the full length of the room along its centerline. This structure extends upward among the permanently installed absorptive wedges of the floor, with the upper surface approximately 1 foot above the tips of the surrounding wedges. To minimize reflections which might otherwise occur from this structure, particularly at the higher frequencies, a set of portable glass-wool wedges is moved over the exposed track structure when full anechoic properties are desired.

To test the effectiveness of these wedges, a point sound source was placed at various heights above the center of the working area of the room. At each height, a microphone was caused to sweep through a horizontal orbit of constant radius about the source. On a given sweep the standard deviation from the mean sound level is a measure of the nonuniformity of absorption. If the area were completely free of absorption anomalies the measured sound level would be a constant, independent of angular position. The results of measurements for a height of 8 feet above the track structure are shown in Fig. 11. It will be observed that the standard deviation from the arithmetical mean level amounts to less than 0.8 db for radii as large as 9 feet, at the frequencies of interest in testing model and full-scale transformers.

Conclusions

It has often been said that measuring a transformer's noise level does not make it quieter. By the same reasoning, more accurate readings obtained in an anechoic chamber will not make the noise any less annoying. However, more accurate data necessarily will provide a better understanding of the problem and will lead to new methods for its solution. The sound laboratory allows more rapid accumulation of data because tests can be made with greater speed and because more transformers can be made available for testing.

The elimination of reflections and the reduction of instrument errors permit the detection of changes of the order of 1 db in transformer noise level. These might formerly have been attributed to errors. Reliable evaluation of changes in the manufacturing process which affect sound level shows that only 1 or 2 db will have an important cumulative effect.

Though the sound laboratory has been in operation only a few months, it has already provided new information which will prove helpful to the users of power transformers. Dynamically scaled models of transformers and various enclosing wall configurations have been tested to give more accurate information for the design of such barriers. The possibility of using auxiliary sound sources to modify the radiation pattern of a transformer and reduce the noise in a particular direction has also been investigated.[7]

SUPERCHARGED cooling of turbine generators was introduced in 1951 with the installation of a 60-megawatt (mw) unit having ducts milled in the rotor copper, through which the hydrogen was forced at high velocity by the use of a 2-stage centrifugal blower. Several similar machines have since been placed in operation and their combined operating experience now exceeds 6 years. Details of design and performance of these units now in service have been fully covered in previous papers,[1,2] and a generator with both stator and rotor supercharging was described a year ago.[3,4]

This fully supercharged generator was built with redesigned mechanical, magnetic, and cooling features to permit maximum utilization of this new ventilation principle. As a result, the generator is specifically designed in all respects for conductor cooling and is more than simply an adaptation of conventional design to the improved ventilating techniques. Many of the component parts of the unit were subjected to laboratory tests before assembly to make sure of the high standard of reliability deemed necessary in such machines. Although its rating is 40 mw at 30 pounds per square inch gauge (psig), tests show that it will carry over 60 mw at 45 psig with maximum temperatures well below the allowable limit.

Building the generator on a development order afforded the opportunity to

test thoroughly and make improvements at all stages of manufacturing without the usual concern for a required delivery date. Shop tests included many different heat runs at a wide range of gas pressures up to 70 psig as well as the usual characteristic curves, reactances, wave form, losses, vibration, and blower performance in air and hydrogen. Nearly 100 temperature measurements were made as often as every 30 minutes during each heat run by means of embedded resistance-type, thermocouple-type, and mercury thermometers placed throughout the entire machine and at various external points. The machine was equipped with pipe fittings and valves for five manometers to study the performance of the newly developed single-stage blower. The results of these exhaustive tests are given here.

Characteristic Curves and Losses

Using the initial test setup pictured in Fig. 1, the zero power factor heat runs, the no-load and full-load saturation curves, open-circuit core loss, direct- and quadrature-subtransient and zero-sequence reactances, and windage and friction loss tests were obtained.

Table I. Comparison of Short-Circuit and Conventional Generator Currents

	Fully Super-charged	Con-ventional
Three-phase symmetrical, rms amperes	11,800	21,000
Single-phase line-to-line, amperes	10,200	18,200
Single-phase line-to-neutral, amperes	13,500	24,600
Mechanical forces at instant of fault, %	31	100

The no-load and full-load saturation curves and the synchronous impedance curve are shown in Fig. 2. The calculated no-load saturation was based on ordinary silicon steel punchings because the availability of grain-oriented silicon iron was not certain at that time. The improved core material was obtained, however, and the saturation curve as well as the core loss was more favorable as a result. The improved permeability and reduced loss agree closely with comparative tests on other machines built with both types of core iron.

It was originally thought that the fully supercharged generator would require well over twice the exciter capacity of the equivalent conventionally cooled generator. Tests indicate 170 kw are required at full load, which is substantially less than twice. A good share of this improvement is credited to the carefully designed magnetic circuit which departs appreciably from conventional design.

It was anticipated that with high gas pressure overloads approaching 200 per cent (%) would be possible, so the fields were designed to permit enough excitation for this load without exceeding 250 volts. Normal generator load is therefore carried with a low exciter voltage, thus accounting for the apparently high field amperes.

The sudden short-circuit currents based upon test values of reactances are compared in Table I with those of the equivalent conventional generator. The last line of the table gives the mechanical forces during a fault in % of those of the conventional generator.

As stated in an earlier paper,[3] the generator nominal rating is based on equalling conventional machine efficiency at full load rather than on temperature limitations. The temperature tests presented in the next section confirm this condition and also show that, if desired, a portion of this temperature margin may be exchanged for even higher efficiency by operating at reduced gas pressure. This step raises the full-load efficiency as well as the fractional load efficiencies well above those for conventional cooling.

Temperatures

In the previous paper[3] it was predicted that the temperature rise of the stator coil strands for full load in 30 psig hydrogen would be that given by curve *A* of Fig. 3. Curve *B* shows the test values of temperature rise of the hottest strand as measured by thermocouples located along the length of the coil. These measure-

B. Test temperature rise of hottest stator coil strand

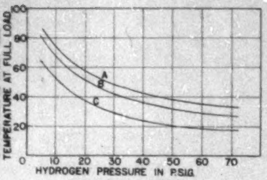

Fig. 4. Operating temperatures as a function of hydrogen pressure

A. Maximum stator strand rise by thermocouple
B. Maximum stator coil rise by detector (located at discharge end of core)
C. Rotor rise by resistance

ments were taken during operation at rated kilovolt-amperes, zero power factor, in 30 psig hydrogen. Since the thermocouples are located on the hottest strand, the temperatures measured include the effect of eddy loss in the hottest strand. Such temperatures are usually not adequately given by temperature detectors between coil sides or under slot sticks. The strand temperature rise at the discharge end of the coil is slightly less than that in the slot portion because the reduced eddy-current losses in the coil ends more than offset the increase in gas temperature.

The effect of hydrogen pressure on the operating temperatures of the fully supercharged generator is clearly given by Fig. 4. The test points through which these curves were drawn were derived from measurements of temperature rise on many heat runs at loads ranging from no load to 60 megavolt-amperes, at voltages up to 16,200, and at hydrogen pressures of 5, 10, 15, 20, 30, 45, 60, and 70 psig. These curves indicate extremely effective ventilation for this fully supercharged machine, not only at higher hydrogen pressures but even at pressures as low as 5 psig. The nearly constant 6-degree temperature difference between hottest thermocouple and hottest temperature detector in the same region is of particular significance, since it indicates that there is very little heat flow through the stator coil insulation and only a small temperature differential between the coil and the core. This fact, coupled with the low average temperature along the length of the coil, as shown in Fig. 3, and the relatively short length of the machine, assures that differential expansion will be minimized.

From the considerations of the preceding paragraph, it is apparent that this machine will have overload capacity at increased hydrogen pressures far in excess of conventionally ventilated machines. This was expected and clearly stated in the earliest publication.[1] Fig. 5 gives a comparison between expected and actual capacity as a function of gas pressure, based on a constant copper temperature corresponding to full load at 30 psig. As rotor temperature is farther below acceptable limits than stator temperature, the latter may be assumed to govern. Curve *D* shows permissible load versus pressure for a hot-spot stator copper temperature rise of 75 degrees centigrade (C), which is still 15 C below the proposed revised AIEE Standard No. *1*[5] and American Standards Association Standard *C-50.*[6] Although it is realized that the overload capacity in kilowatts can seldom be fully utilized, due to turbine or boiler limitations, the increased kilovolt-amperes available from the fully supercharged generator make it an attractive machine from the standpoint of kilovar overloads.

Temperature rises of the mechanical parts of the fully supercharged machine were also very favorable. Of special interest are the temperature rises of some of the components considered to be design innovations.[4] These may be briefly discussed as follows:

Collector Rings and Brushes. These were painted with special temperature sensitive paint. This paint indicated, after all heat runs had been completed, that no part of the rings had reached 115 C total temperature, which was the calibration of the lowest temperature paint available. The rings had operated during five heat runs for which the excitation kilowatts were 44% above full-load excitation. Tests on this unit and on other 3,600-rpm generators show that 80 to 90% of the collector ring heat loss is due to surface friction, hence resistance loss is not the limiting factor as it is on slower speed machines. The small diameter ring used on this machine reduces the major heat loss, so that cooler rings as well as brushes result. The brush holder temperature rise by thermocouple at the highest field current was 30 C.

Finger Plates. Temperatures of the individual tooth finger plates[4] were measured by thermocouples. The temperature rise at either end of the core did not exceed 43 C at full load under the lowest hydrogen pressure of 5 psig. This result is quite encouraging and proves that the high ampere conductor loading of the fully supercharged machine is no hardship for these clamping fingers.

Bushings. The radiator-type jet-cooled bushings also were highly satisfactory.

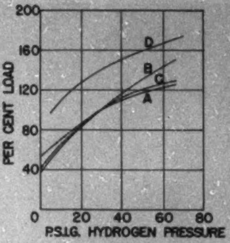

Fig. 5. Expected and actual capacity as a function of hydrogen pressure

A. Expected capacity at full-load temperatures
B. Test rotor capacity at full-load rotor temperature
C. Test stator capacity at full-load stator temperature
D. Permissible load for 75 C stator hot-spot rise

The maximum temperature rise of the bushing itself, measured by a thermocouple located at the outer extremity of the stud, was only 27.4 C at 60-megavolt-amperes, 30 psig. The temperature rise of the outer shell near the bushing was 19.4 C.

Operation of Seals and Other Design Features

Many of the design improvements merit individual comment, but as this is beyond the scope of the present paper only a few observations and test results will be given. As previously described,[3] the stator windings are suitable for a range of voltage ratings by the omission of fractional turns. One turn per phase was cut out during the shop tests. The long air gap was believed well suited for such winding modifications and the test results did not indicate excessive rotor temperatures. Utilization of this feature is only possible because of the liberal stator coil thermal margin as substantiated by tests.

One of the purposes of testing over a wide range of gas pressures was to observe the behavior of the hydrogen seals. Test floor facilities limited operation to 70 psig. At this pressure in either air or hydrogen the sight flow gauges indicated only a mere trickle of oil was being admitted to the hydrogen side of the seals. The hydrogen leakage at 70 psig was within shop safety requirements despite the many pipe connections for manometers and thermocouples that were brought out of the generator.

Vibration records were made at many points on the generator shell, bearings, and elsewhere and, as expected, were found to be well below similar measurements on the relatively large conventionally cooled machines of equal rating. Observations during assembly and tests showed that the end cover V-clamps, the air gap baffle, seals, and auxiliary parts were easy to install or dismantle and conformed in every way to expectation.

Improvements relating to the rotor were equally successful. The machine was in good mechanical balance at all loads and temperatures. The long air gap and internal cooling of the windings permitted omission of the usual rotor surface grooving. The lower noise level of the smooth rotor was especially noticeable during shop balancing runs.

Perhaps the most gratifying of all test results was the splendid performance of the new single-stage blower developed after a series of experimental tests with quarter-scale models. Pressure measurements exceeded by 20% the highest measured pressure on any of the 2-stage blowers previously tested, while power input per cubic foot per minute was materially lower. The improved blower efficiency permits this machine to operate safely in air because the air temperature undergoes only a moderate rise in passing through the single-stage blower. With adequate cooling water of low temperature, substantial loads may be carried in air.

The behavior of the axial flow coolers was also found to be highly satisfactory. As most of the test floor cooling water supply was needed for the 66-mw unit with which the load heat runs were made, the fully supercharged machine had to be tested with the limited drinking water supply. Less than 25% of rated water flow was provided, but since its temperature was somewhat below the specified value, inlet hydrogen did not exceed 40 C except during the 60 and 70 psig tests where it rose to 42 C and 43 C respectively. Inlet temperature in air at 2 psig was less than 40 C under the test conditions with reduced water flow.

The exciter for this generator is to be of the a-c commutatorless type similar to one built and tested a year ago[7] for a 35-mw unit. In addition to eliminating the commutator, brushes, and all rotating windings, the device incorporates a continuously acting voltage regulator of superior speed and reliability. Also it permits direct-connected 3,600-rpm exciters on fully supercharged generators of any capacity now contemplated.

Conclusions

It may be concluded from the foregoing that the shop tests of the fully supercharged generator confirm the complete adequacy of its design and substantiate the predictions presented in earlier papers. The new single-stage blower yielded considerably more pressure than the earlier 2-stage blowers and a substantial efficiency improvement. The excitation requirements are well below expected values and temperatures are low on both stator and rotor.

The efficiency at normal gas pressure is equal to that of the conventionally cooled unit at full load and higher at reduced loads. Because of the temperature margin, operation at low hydrogen pressures is shown to be permissible and to raise efficiencies at all loads. This pressure adjustment may be governed by temperature of the embedded resistance detectors between coil sides at the discharge end of the stator, as these temperatures are only 6 C below those of the hottest strands. If temperatures are allowed to approach within 15 C of permissible standards, an enormous overload is possible either in kilowatts or kilovars. Because of the high blower efficiency, the tests indicate operation in air to be possible at a load depending upon the temperature and quantity of cooling water available.

The fully supercharged generator is considered a great forward step because of its many economies and advantages to the utility. Among these are savings in power plant space; lower crane, foundation, and switchgear costs; reduced differential expansion; and less maintenance. Ratings up to 200 mw can be built of this design without exceeding the physical size of the 3,600-rpm conventionally cooled rotors previously built by Allis-Chalmers. High-quality rotor forgings at this size are more easily obtained than the larger sizes. The cooling ducts milled in the copper conductors permit reducing the stresses in rotor bore, tooth root, wedges, and retaining rings. The 200-mw unit could be shipped assembled from the factory without resorting to the cartridge design of the stator.

The gas volume of the supercharged generator with its compact, axially cooled stator core and external cooler housings will be a small fraction of that of the conventional type, and therefore pressure changes with load to keep efficiency high at all loads are economically possible.

With materials now available, it is safe to say that fully supercharged generators up to 300 mw are possible at 3,600 rpm. Application to 1,800 rpm is definitely feasible but will require separately driven high-speed blowers since adequate pressure at 1,800 rpm would involve a prohibitive blower diameter.

Steam Turbine-Generator Operating and Maintenance Methods of the Southern California Edison Company

C. L. SIDWAY
MEMBER AIEE

C. M. CLEVENGER
MEMBER AIEE

Synopsis: This paper provides selected information related to the operation and maintenance of steam turbine generators, as practiced on the Southern California Edison Company system. The methods outlined are the result of years of progressive development and necessarily reflect the predominant characteristics of the system which they serve. Certain of these characteristics will be outlined as the basis for a better understanding of the existing operating methods.

The System and Its Operation

The System

Graphically, the Edison major 220-kv transmission system is wye-shaped, Fig. 1, with the principal sources of generation at the extremities of the wye, and with the major load center at the convergence. One arm of the wye, extending 250 miles northward, terminates at Big Creek, in the Sierra Nevada Mountains of Central California. In the Big Creek area some 530 megawatts (mw) of hydrogeneration are located. Five 220-kv substations are located along the four parallel transmission lines which comprise this arm of the wye, supplying power to intermediate loads. In addition, one 250-mw interconnection with the Pacific Gas and Electric Company is made at the approximate mid-point of the arm, while a 110-mw interconnection with the same utility exists closer to the Big Creek generation area.

The alternate arm of the wye crosses the Mojave Desert, extending 300 miles eastward to Hoover Powerhouse on the Colorado River. Approximately 400 mw of generation are available at this location. Of the three 220-kv transmission lines which comprise this arm of the wye, two reach the load center in Southern California without intermediate taps, while the third line has interconnection points with the state of Arizona at Davis and Parker Powerhouses and, in addition, serves two groups of pumps on the Metropolitan Water District Aqueduct between Parker and the Edison Highgrove Substation in Southern California.

The stem of the wye, approximately 20 miles in length, connects the Long Beach Steam Plant No. 3 (220 mw) and the Redondo Steam Plant No. 2 (156 mw) to the 220-kv system. Available in the same area, at 66 kv, are the Long Beach Steam Plant No. 1 (22 mw), the Long Beach Steam Plant No. 2 (174.5 mw), and the Redondo Steam Plant No. 1 (288 mw). The Etiwanda Steam Station (280 mw), located near the eastern edge of the major load center, supplies power to the 220-kv system and to the local 66-kv load.

Pacific Southwest Power Area

The Pacific Southwest Power Area, of which the Southern California Edison Company is a contributing member, embraces an area of approximately 380,000 square miles. On October 1, 1954, there existed a total installed capacity of 8,800 mw of generation, about equally divided between hydro and steam. The coincident peak during the summer of 1954 amounted to 7,737 mw.

The Edison system contains 2,187,420 kw of effective operating capacity of which 52 per cent is steam. During the first seven months of 1954, steam production amounted to 58 per cent of the system total. Edison operates in parallel continuously with three other systems and, from time to time, with two additional systems under automatic tie-line load control. It is present practice that one of the systems will assume frequency regulation of the combined systems, usually employing time-error correction, while the other systems control their ties with the frequency-regulating system, normally using tie-line bias control.

Under prevailing conditions, the load changes on the systems and interchange of power across the interconnecting ties will on occasion impose rate-of-generation changes of 25 to 30 mw per minute for periods of relatively short duration. The use of multiple plant regulation within any one of the systems has not been adopted, the load control, or frequency regulation, being assigned to one generating plant at a time. While the indicated rate of change in generation is sporadic, it does require that the regulating or controlling station be capable of manipulating its generating units appreciably.

On the Redondo Steam Plant No. 1, which has automatic combustion control, no difficulty is experienced in handling the indicated load changes. The control is less satisfactory when using some of the older steam plants where the limiting factors are often related to thermal expansion and contraction phenomena in the steam cycle and, in some cases, to the auxiliary equipment, especially the boiler feed pumps.

Load Allocation

The problem of load allocation between hydro and steam generation and between numerous and varied generating plants is complex. To attempt to detail accurately the many factors which must be evaluated to define wholly the procedure is beyond the scope of this paper. However, it may serve the intended purpose to indicate some of the more influential factors.

In hydrogeneration it is important that maximum utilization of available water be accomplished even though it is not possible to know with certainty when such water will become available, either from rains or melting snow. This requirement assumes particular significance in the case of stream-flow plants, which have no storage facilities. Adding to this problem is the need for meeting contract commitments for release of water to users in the lower valleys, and the further need for staying within maximum permissible limits for storage of water. Experience indicates that about 85 per cent of the normal runoff will occur between April 1 and July 30. Further complicating the water-use problem is the diversity of available water sources where certain generating plants in tandem arrangement effect joint use of water and where converging streams in the lower canyons add to the supply available to lower canyon plants.

Much of the planning and scheduling of steam generation and maintenance is hinged on the aforementioned factors. In the dry years, as much steam as possible is operated as base load generation, and capacity factors tend to approach unity. To make certain that sufficient

Paper 55-119, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing December 8, 1954.

C. L. Sidway and C. M. Clevenger are with the Southern California Edison Company, Los Angeles, Calif.

fuel will be available for these maximum requirements for steam generation, minimum-use provisions are included in fuel contracts. During wet years, these provisions force the use of steam generation at times when the economics of the situation might not so dictate and must accordingly be considered, along with the hydro limitations, in arriving at a load allocation schedule. The steam generation plants serve as a source of kilowatt capacity to meet system load requirements, including spinning reserve requirements associated with either normal or emergency operation, although steam is not the sole source of spinning reserve. Steam generation also must provide the kilowatt-hours of energy to meet system load requirements which are beyond the ability of hydro sources to provide.

The more modern steam plants on the Edison system operate with a capacity factor approaching 90 per cent, and have on a few occasions exceeded this figure, while the older plants operate with a capacity factor less than 90 per cent. As implied previously, this factor is directly related to the water yield in hydro. The over-all steam division capacity factor for the last 4 years has fluctuated between 46 and 80 per cent. Additional items influencing the yearly capacity factor are the programmed and unprogrammed outages required to maintain the extensive auxiliaries involved in steam generation.

The sequence of loading and unloading the steam generating plants conforms to rigid economy factors. Thus, the load increases are normally made at the plant which can make them at the lowest incremental cost rate. Conversely, the load reductions are usually made on the plant operating at the highest incremental cost rate. The steam plants are responsible for the placement of assigned loads to the individual units according to incremental heat rates.

Wherever practical, block-loading increments are assigned on the basis of operating the units at the wide-open valve positions. This philosophy applies as well at the full load point of the generator, except where limited by boiler capacity. This practice is followed to minimize the effect of the throttling losses.

SYSTEM SEPARATION

During periods of general instability or persistent low speed, the system is set up to separate automatically into load areas, each area containing sufficient generation to carry the isolated load, with some spare capacity. One such load area is that associated with the group of steam generating plants. In case the automatic separation does not occur within 15 seconds and the instability still persists, a manual separation is performed at all main separation stations where such instability is being observed, without regard to the indicated frequency at the station.

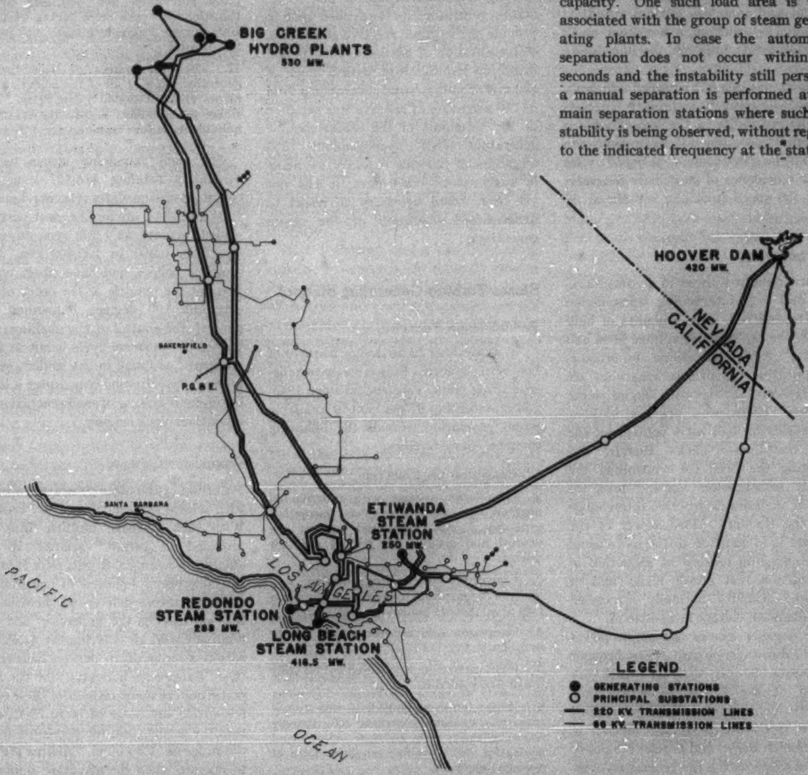

Fig. 1. Southern California Edison Company, major generating stations and transmission system

If, following the main separations, it is found that one of the steam plants is out of step with the other steam plants in the isolated steam load area, then further manual backup separations can be made to isolate the case of trouble, thereby maintaining maximum continuity of service. These delayed manual backup separations are not made until after at least 20 seconds have elapsed. Within isolated systems formed by separations, if instability still persists, the 220-kv switching centers may order load dropped or further sectionalizing.

In the generating stations with multiple generators, generators which are not obviously out of step with each other but which have rejected load and are apparently out of step with the system are kept on the line for at least 1 minute unless there is some compelling reason to do otherwise. Every effort is made to restore and maintain normal speed, as indicated by machine tachometers, on all generators remaining on the line during periods of instability.

During periods of low speed which are not accompanied by instability (suggesting the possibility of the loss of a block of generation), manual separations are made if the speed remains below 57 cycles with no evidence of immediate recovery, or if the speed is falling rapidly at 57 cycles.

VAR LOADING

With remote sources of hydrogeneration and long intervening transmission lines transferring large amounts of bulk power, the problems of voltage level and reactive generation assume importance. Complicating the picture somewhat are the high-capacity ties with the adjoining utilities. These ties operate without the benefit of load ratio control on the main transformer banks, thereby emphasizing the need for controlling the 220-kv transmission voltage level to prevent undesirable reactive interchange over the tie lines. This aspect of the problem is in addition to the more usual and compelling reasons of reduction in transmission real power losses and of increased stability normally associated with adequate voltage level control.

The existing sources of reactive power on the Edison system are: 1. synchronous condensers, 90 per cent of which are located at the 220/66-kv substations; 2. static capacitors, which are applied at the distribution voltage levels; 3. transmission lines; and 4. reactive power realized by operating the generators overexcited.

The availability of load ratio control at the majority of the 220/66-kv substations makes it possible to vary the condenser kilovar generation over a wide range and still maintain desired 66-kv bus voltage. The 66-kv stations having load ratio control are given condenser reactive generation schedules which in general call for maximum boost during the heavy-load period, and maximum buck, or a value of reactive generation which will bring the 220-kv banks to unity power factor, during the light-load period.

The steam station generators are operated close to unity power factor, generally in the range of 0.98 to 0.99 lag. Basically, they are considered as a reserve source of reactive generation. During periods when there exists an abnormal system reactive demand, or when a forced outage of a large synchronous condenser or long transmission line occurs, steam station generators are then called upon to provide the required reactive generation. Representative of the heavy-load period operating requirements, with a block of 679-mw of on-line steam generation a total of 119 megavars of reactive was supplied at the terminals of the steam turbine generators. With approximately 500 megavars of bucking capacity available in synchronous condensers, it has not yet been found necessary to resort to underexcited operation of the steam generators.

Steam Turbine-Generating Stations

BASIC DESIGN FEATURES

An analysis of basic design features of Southern California Edison steam turbine-generating plants constructed since 1945, and representing 67 per cent of available steam generation, reveals the following common characteristics:

1. Generators are 3,600 rpm.
2. Generators operate with ungrounded neutrals, and have single-phase potential-type transformers connected between the neutral and ground for ground detector alarms.
3. Generators are hydrogen-cooled, and most have maximum hydrogen pressure ratings of 30 pounds per square inch (psig).
4. Generator armature voltages are 13.8 kv or 18 kv.
5. Field excitation is provided at 250 volts d-c or 375 volts d-c.
6. With a few exceptions, field excitation is supplied by motor-generator sets, usually one per unit with common spare, and operating with rotating amplifier type of voltage regulators.
7. Generators are wye-connected and supply power to the system through main transformer banks which are delta-connected on the low-voltage winding, and wye-connected on the high-voltage winding.
8. The largest single generator carries a 1/2-psig hydrogen rating of 147,059 kva at 18 kv, with the smallest unit rated 70,588 kva at 13.8 kv.
9. With the exception of the Redondo Steam Plant No. 1, power for auxiliaries is supplied at 4,160 volts from auxiliary generators located on the shaft of the main unit, with reserve backup from the system through step-down transformers.
10. Relay protection for the main generators consists principally of generator differential protection and unit differential protection. The latter establishes a protective zone encompassing both generator and transformer and generally serves as backup for the faster generator differential relays. Negative-sequence relays are being installed on three large units on a trial basis.
11. Steam conditions on the earlier Redondo Steam Plant No. 1 units are 900 degrees Fahrenheit and 850 psig at the throttle, while the more recent units are 1000 degrees Fahrenheit and 1,800 psig at the throttle.
12. The unit system of boiler-turbine-generator exists at all of the modern steam plants except Redondo Steam Plant No. 1, where seven boilers supply the steam requirements of four turbines.

The eight remaining steam turbine generators totaling 416,167 kva with initial operating dates varying between 1924 and 1943, are for the most part air-cooled, operate at 1,800 rpm, range in size from 6,000 to 100,000 kva, have multiple boilers, and have steam conditions at the throttle of the order of 375 psig and 700 degrees Fahrenheit. In general, the control of the auxiliaries involved in the steam cycle is not as fully automatic as found in the modern steam plants; this situation constitutes a limiting factor in the use of such generation for other than block loading.

GENERATOR COOLING

Certain of the older generators operate with closed-system, forced-air cooling. With such systems, multiple fans are provided to permit variation in the amount of cooling with generator loading. The practice is followed of maintaining the temperature differential between the hot air leaving the generator and the relatively cold air entering the generator within a range of 20 degrees centigrade (C). Experience indicates that the normal armature temperatures for these units lies within the range of 60 to 75 C, and that the normal field temperatures are in the range of 70 to 90 C. Alarms are set to operate when the armature temperatures reach 85 C, with supplemental instructions not to exceed 100 C, while the alarms on the field are set at 110 C with instructions not to exceed 125 C.

The generating plants of more recent design operate with hydrogen-cooling of the generators, based on maintaining acceptable cold gas temperatures. Normally, the cold gas temperatures are not allowed to exceed 40 C. If the cold gas temperature exceeds 40 C, additional hydrogen is added. When the cold gas temperature drops below 40 C, the first step taken is to remove the more costly condensate cooler from service. If further action is required, the hydrogen pressure regulator valve is set at a lower value, and the machine pressure allowed to decrease by normal leakage. At loads below 60 mw on 78-mw units, decreases are made in hydrogen pressure to a minimum of 1/2 psig, when justified by prevailing cold gas temperature.

Emergency Procedures

With auxiliary generators located on the shafts of the main units, and also constituting the normal source of energy for the auxiliaries, any departures in speed of the main units are directly reflected in similar departures in speed of the auxiliaries. This is an important factor in establishing emergency operating procedures.

In the event of loss of field of a main generator, the following instructions apply. As soon as it has been verified that loss of excitation has occurred, most of the net load on the unit is removed as rapidly as possible, using the fast position of the load limit followed by immediate opening of the circuit breakers connecting the unit to the system. The unit speed is then re-restablished at its normal 3,600-rpm value to restore the speed of auxiliaries. This is particularly important for certain key pumps. All important supervisory instruments are checked for possible clues as to the source of trouble, or any damage which may have resulted therefrom. The system dispatcher is notified as to the location of the loss in generation.

If the supervisory instruments do not indicate that damage to the unit has occurred, an attempt is made to restore excitation to the unit, using the spare exciter where available. If successful, the unit is synchronized to the system and reloaded, meanwhile observing its performance during the loading period. If unable to restore excitation, and supervisory instruments and other checks indicate no known mechanical trouble, the unit is allowed to idle, carrying its auxiliary load, while an investigation is made. Subsequent procedure is then determined by facts established for the individual case.

The operating procedure in the event of out-of-step operation, assignable to causes other than loss-of-field, are generally identical with those indicated in the foregoing for that condition. Because the influence of out-of-step generators may be detrimental to the satisfactory operation of other machines on the line at the time, it is generally considered preferable that such unstable machines be removed from the system as rapidly as practicable to the extent permitted by spinning reserves and other emergency procedures which may be invoked. Where single generators are out of step with other generators in the same plant, ordinarily indicated by high unit speed and low kilowatt load, the unit is immediately removed from the line and resynchronized as soon as possible, following a few precautionary checks of supervisory instrumentation. When multiple generators in the plant are not obviously out of step with each other, but have rejected load and are apparently out of step with the system, usually the generators are kept on the line for at least 1 minute unless there is some compelling reason to do otherwise. Every effort is made to restore and maintain the normal speed (as indicated by machine tachometers) of all of the generators remaining on the line during period of instability.

If a generator relays on differential, and the generator is not urgently needed for system operation, the generator and all related and pertinent equipment are thoroughly checked for contributory causes before restoring the generator to service. When a generator relays on differential, and the generator is urgently needed for system operation, the following procedure applies:

1. If the relay operation is known to be faulty or accidental, and there is no accompanying voltage dip such as would be produced by a short circuit, an attempt is made to restore normal speed and voltage and, if successful, to return resynchronized to the system.

2. If the cause of the relay operation is not immediately known, the relayed equipment is inspected for evidence of trouble. If the inspection suggests that the contributory causes are related directly to the generator, thorough tests are made before restoring the generator to service. If the inspection indicates that the trouble is external to the generator, efforts are made to correct or isolate the trouble to permit restoring the generator to service. If the inspection reveals no apparent cause for the relay operation, the system dispatcher is so advised and preparations are made to restore normal machine speed and voltage and return to service.

Start-up Procedures

In the startup of steam turbine generators from a cold start, very little difference exists in procedure applicable to generators of varying age and manufacture. The essential difference being in the point of application of field to the generator. In the 1,800-rpm category, field is applied on Edison units at 350 rpm, while in the 3,600-rpm group, two selected points of field application obtain, these being 50 rpm on one block of generators and 3,000 rpm on another block, conforming to manufacturers' recommendations.

The following description is illustrative of start-up practice on a selected group of 3,600-rpm generators, and is predicated upon all of the requirements of a rather extensive procedure for preparing the turbine and related auxiliaries for operation having been met satisfactorily.

With the unit on turning gear, an inspection is made of certain critical items such as lube oil levels, hydrogen pressure and density, shaft eccentricity, and a test of admission valves for freedom of operation. The unit speed is increased to 50 rpm and tripped, and an audio check is made for possible rubbing or binding in the turbine generator. The speed is thereafter increased to 400 rpm over a 10-minute period. This speed is maintained for 30 minutes and, in the interim, the shell temperature, vibration, and eccentricity are observed on the unit recorders. If operation appears satisfactory, the speed is then increased gradually to 3,000 rpm, and field current is applied to the generator. Further increase in speed to 3,600 rpm is made and the unit placed on governor control. The time interval from 400 to 3,600 rpm requires approximately 40 minutes. Thus a total of 80 minutes have elapsed from the initial roll to the point when the unit is placed under governor control. This typical 78-megavolt-ampere generator is then synchronized to the system and loaded to 10 mw and held at that load for 20 minutes while certain major items are re-examined, following which the unit is released for normal operation. The practice of field preheating on steam turbine generators is not employed on the Edison system.

Shut-down Procedures

Under normal conditions, the existing load on the generator is removed at a rate of 1 mw per minute. When unloaded, an underspeed release test is made and the field removed from the generator. Trip tests are performed for low vacuum, low oil, and over-speed conditions. After a test of governor range, the unit speed is readjusted to 3,600 rpm and the unit tripped manually.

In the case of the older units, when the generator is off the line with the throttle valve tripped and the machine decelerating, the field current is reduced to near minimum, and this field entirely removed about 30 seconds before the unit stops rolling. It is a general rule, applicable to steam generating units on the Edison system, that it is permissible only in an emergency to increase the field current to shorten the deceleration period. In an extreme emergency, when an immediate shutdown of a unit is necessary, the turbine throttle valve, or stop valves, are tripped closed as quickly as possible and the generator circuit breakers are opened immediately. The decision to increase the generator field current to force the machine to decelerate in a shorter period or the decision to open the generator field breakers of the older generators and allow them to come to rest without a field is left to the judgment of the operating personnel on shift, who are guided by the nature of the emergency.

Generator Maintenance Procedures

It is the objective of the maintenance program, as followed by the Southern California Edison Company, to confine failures to determinable periods consistent with operating schedules to the fullest extent possible. To realize this objective requires added emphasis on the preventive aspect of maintenance and the use of test procedures which on occasion may appear to be severe, particularly to those who are remote from the over-all problem.

ROUTINE OUTAGES AND OVERHAULS

Routine outages on main units are conducted at all plants on a maximum interval of 90 days. These outages are usually confined to an 8-hour period, intended to provide an opportunity to check all functional equipment intimately related to operation of the units and is, in effect, a verification test of turbine-generator safety devices. The basic 90-day interval may be shortened if adverse insulator contamination should develop. Trip tests are performed on circuit breakers; governor operation is checked; brushes, slip rings, and commutators are closely inspected; insulators are washed or wiped; and safety devices are carefully tested. Some short-time work is accomplished during the outage. The steps outlined in the foregoing for normal shutdown constitute a part of the routine outage procedure as well as a part of the routine overhaul.

Overhauls on main units are conducted on a basic 3-year interval. On alternate overhauls, the generator rotor is removed to permit a more extensive inspection. A detailed account of items covered during overhauls is outlined in the following.

PRELIMINARY EXAMINATION

Prior to the routine overhaul, the operating records are examined for information suggesting a need for a more detailed inspection of the subject generator. Historical reference is made to the supervisory instrumentation covering main bearing vibration, bearing oil pressures, hydrogen pressure, purity, losses and temperature, and a correlation of these factors with generator loading. An inspection is also made to determine the amount of maintenance work directly required for the supervisory instruments.

MAIN BEARING AND SEALS

Bearing and seal clearances have varied sufficiently throughout the life of the generators to justify inclusion in the overhaul program. In general, maximum permissive clearance limits in the range of $1^1/_3$ to 4 mils per inch of shaft are considered satisfactory, the exact value depending on certain qualifying factors such as the age of the machine. Bearings are inspected for high spots, wear, pinching caused by excessive shims, and for foreign matter imbedded in the babbitt. The bearing insulation is carefully wiped, washed with naphtha or solvent, and dried and meggered.

BEARING OIL SYSTEM

Bearing oil pressures are compared with standard factory recommendations. This item has not been a source of trouble. An inspection is made for indication of exterior leakage around the bearings and piping, and for cleanliness of lube oil coolers, strainers, and tanks. The condition of the bearing oil is observed. More exhaustive oil analysis is made by operating personnel as a part of normal operation.

HYDROGEN SYSTEM INSPECTION

If comparison of hydrogen losses with permissible limits suggested by the manufacturer indicate excessive use, a thorough check of coolers and piping is made and corrective action is taken. Variations as great as twice normal in such losses have been experienced.

Piping and valves in the related cooling water system are inspected for visible leaks to ascertain that the valves are operable. Coolers are examined for tube deposits and wire brushed if necessary. The use of condensate has minimized the amount of cleaning required in the coolers. Hydrogen cooler vents are checked for proper functioning, for placement, and for loose or broken joints in the vent lines.

Following overhaul, the hydrogen system is tested under operating pressure by soaping in the disturbed area, or with a haloid torch and freon gas with the unit in air, the choice dependent on the type of unit. The instruments associated with the hydrogen system are calibrated each time the system is purged. Hydrogen alarms are tested before returning to service.

GENERAL CHECK LIST

Generator moisture detectors and alarms are examined. Shell temperatures are checked when returning the generator to service. The control wiring is inspected and meggered where practicable. Voltage regulators are serviced and tested. The supervisory instruments and associated remote pickups are inspected, tested, and calibrated.

On the older units, the generator bus is meggered; this test is omitted on the newer units employing numerous post-type insulators because it has not produced consistent results. Necessary testing and preventive maintenance work is performed on associated exciters, main circuit breakers, field breakers, and rheostats. Added emphasis is placed on the importance of circuit-breaker work, especially as related to possible single-phase operation of the generators.

GENERATOR STATOR, ROTOR IN PLACE

The stator winding is meggered in hydrogen. If conditions appear favorable, the established a-c overvoltage test, computed as 150 per cent of the highest a-c operating voltage, is applied. Among the determining factors in the application of the overvoltage are the general level of the megger readings, the related polarization index, and any unusual conditions observed during the megger tests. If it appears reasonably certain that application of the standard a-c overvoltage test will result in breakdown of the winding, a preliminary test using direct current may be performed.

The generator is purged of its hydrogen, and the hydrogen coolers are removed for the remainder of the inspection. The general appearance is checked for oiliness, moisture, or unsatisfactory insulating varnish. Winding is inspected for any insulation abrasion which might indicate presence of foreign material.

Coil ends are examined for possible distortion. The security of all lashings, spacer blocks, and coil support brackets is established. Coils are inspected for tape separation, progressive balling of insulation, and for excessive sponginess. Conditions found are recorded on a chart for future reference. Coils are examined for evidence of corona attack.

Any progressive armor separation in the conducting paint belt is noted. Wedges and filler strips are checked for movement or looseness. Immediate area is searched for broken pieces of laminations, wedges, or foreign metallic particles. The stator iron is inspected to the extent possible for working, and for indications of moisture or of hot spots. Tightness of core bolts and finger plates is determined by inspection and tests.

GENERATOR STATOR, ROTOR REMOVED

In addition to a more comprehensive examination of the requirements outlined in the foregoing, the generator stator is further inspected for the following conditions:

1. Coil movement in slot.
2. Damaged, missing, or loose wedges.
3. Foreign material in ventilating ducts.
4. Stator iron for indication of hot spots and moisture.
5. Iron oxide deposits adjacent to brackets.

GENERATOR ROTOR, IN PLACE

The rotor winding is meggered in hydrogen. A routine d-c overpotential test is applied to the field winding. This test voltage has been established as 180 per cent of the a-c test value formerly employed, the exact value being related to maximum operating field voltage. The coupling faces are checked with feelers for alignment, and a coupling rim check is made with feelers and a nonmagnetic dial tester. Coupling bolts and rotor fan blades are checked for tightness. Collector ring insulation, stud assemblies, and brush assemblies are checked for alignment, clearances between brush box and ring, and for wear, cleanliness, and mechanical integrity.

GENERATOR ROTOR, REMOVED

In addition to a more comprehensive examination of the requirements previously outlined, the generator rotor is further inspected for these conditions:

1. The retaining rings and centering rings are inspected for tightness and for evidence of working, burning, and for discoloration, particularly between ring fit and rotor body.
2. Clearances between wedges and retaining rings are checked.
3. The rotor surface is examined for indication of foreign matter having been in the air gap, and for evidence to local heating.
4. The winding bracing blocks are inspected for movement, and the winding for general appearance.
5. All ventilating passages are checked for cleanliness.
6. The bearing journals are inspected for wear, eccentricity, and grooving, particularly if the unit has been operated for any appreciable periods on turning gear.
7. Shaft and retaining rings are magnafluxed.

Conclusions

The policies and procedures outlined have been in effect on the Southern California Edison Company system since about 1945. During this period no generators have failed in service.

It is hoped that this exposition of the operating and maintenance procedures applying to a system involving widely separated, mixed hydro and steam generating plants, and long, high-voltage transmission lines will be of value to other power system engineers.

Development of Small Hydroelectric Sites in Western North Carolina

H. H. GNUSE, JR.
MEMBER AIEE

IT HAS been economically possible to develop several small hydroelectric sites in Western North Carolina during the past 5 years by incorporating in the structures only those mechanical, structural, and electrical components that are actually required to produce electricity safely and reliably with a minimum of operating and maintenance expense. The use of the rock fill, earth-faced type of construction for the dams has been a major factor in providing a low-cost design. Also, the installation of supervisory control and telemetering to permit operation of the new plants by personnel located at existing plants has greatly reduced operating costs, thereby contributing to the economical development. The use of protective coatings of stainless steel on vulnerable turbine parts has been a major factor in reducing long-term maintenance costs.

Electrical Design Features

All of the recent installations have utilized remote control in some form to eliminate the need for operators at the new plants. For those plants that have been located within a radius of approximately 1 mile from an existing attended station, it has been found most economical to transmit the power output of the plant at generator voltages to the attended station where the generator oil circuit breaker is located, along with the associated metering, relaying, and synchronizing equipment. With such an arrangement, the remote station can be controlled by a 19-conductor cable of no. 19/25 American Wire Gauge utilizing the battery voltage supplied from the control station, thus eliminating even the need for a station battery at the remote plant.

Those plants that are located too distant from the control station for the economical transmission at generator voltage are controlled by supervisory and tele-

metering equipment operating over a pair of telephone wires or over a single carrier-current channel. Since the application of such supervisory control and telemetering equipment has already been described,[1,2] a detailed explanation of the functions and operations of this equipment will not be given. It should suffice to point out that, consistent with the basic design consideration of limiting the installation to equipment that is actually required for safe and reliable generation, the supervisory and telemetering equipment has been kept to a minimum. With the multitude of functions that can be accomplished by supervisory control and telemetering, it is usually difficult to determine just where to stop with such an installation. It is obvious that if an unnecessarily large amount of such equipment is installed, it becomes increasingly more difficult and expensive to maintain, and the added cost of the unnecessary equipment offsets a portion of the economical gains that it should normally afford.

For these installations, supervisory control is used to accomplish the following:

1. Start and stop the unit.
2. Adjust the kilowatt output of the unit.
3. Adjust the kilovars of the unit.
4. Open and close transmission-line sectionalizing devices in the substation when such are installed.
5. Sound an alarm for operation of any of the relays or for indication of high or low reservoir elevation.

Telemetering is used for the following indications:

1. Generator kilowatt output.
2. Generator kilovar output.
3. Generator voltage.
4. Level of water in reservoir.

It will be noticed that only one annunciator alarm indication is used. This decision was based on the conviction that in case of an alarm a man must be dispatched to the station to correct the trouble, and that little added benefit would be gained by providing the operators at the control plant with specific information as to the exact nature of the relay operation. When the attendant reaches the remote plant, he can determine the cause of the operation from the station annunciator and report to the controlling station. In the meantime, the operators at the controlling station can determine the seriousness of the alarm by checking their telemetered readings or by checking to see if the machine will restart if it has been automatically shut down. The protective circuits at the remote plant are arranged so that the machine locks out for relay operations indicating serious trouble, such as operation of the differential relays, generator ground relay, low battery voltage, hot bearings, etc.

It will also be noted that no supervisory control or telemetering is used for operation of the taintor gates. They are controlled by float-operated devices which, when the lake has reached its maximum operating level, automatically position the taintor gate to discharge the stream flow in excess of the turbine discharge. Such automatic devices not only save considerable investment cost in supervisory control and telemetering but also relieve the operator at the remote station of the time-consuming chore of constantly checking the lake elevation and adjusting the taintor gate opening during periods of high flows. A high water alarm is incorporated in the annunciator circuit to sound an alarm should the water in the reservoir rise above a predetermined level, indicating that the taintor gate controls had not functioned properly.

All of the recent developments have been single unit stations. The need for station service supply when the generator is shut down has prevented the application of a unit transformer-generator installation with high-voltage circuit breaker, and it has been necessary to install the oil circuit breaker between the generator and the step-up transformer bank. Since this low-voltage oil circuit breaker could provide all the protection required except for faults within the transformer itself or on the transformer busses, which faults should be very rare in occurrence, a high-voltage oil circuit breaker has been omitted and a combination air break switch and ground switch utilized. In case of operation of the differential or case ground relay on the transformer bank, the high-speed ground switch places a fault on the line which trips the feeder breaker at a remote substation and simultaneously initiates the trip circuit to the gang-operated air break switch so that it will be opened before the line can be manually reclosed.

Generator protection is provided by a conventional neutral ground current transformer and relay and by double-primary current transformers which operate a sensitive plunger-type overcurrent relay for differential protection. By using a low ratio on this double-primary current transformer, more sensitive relaying can be obtained at much less cost than with the conventional generator differential relay.

Another somewhat unconventional electrical design feature is the use of the station service secondary voltage for supplying synchronizing potential on the transformer side of the generator breaker. This eliminates the need of additional potential transformers for this purpose and has proved entirely satisfactory in actual operation.

Mechanical, Structural, and Hydraulic Design Features

The powerhouses for these projects have been built large enough to accommodate the unit with its associated switchgear with provision for only enough unoccupied space to store the rotor when the unit is disassembled. No control rooms or offices have been included in view of the fact that the plants are all remotely operated. The switchgear and switchboards are placed on the generator floor which is usually level with the top housing of the generator stator.

For those installations where a steel pipe line is required, the design has taken into consideration the inherent self-supporting strength of the pipe to require a minimum of supporting bents. On one installation which required 2-foot diameter pipe, the bents were spaced at 64 feet, and in order to provide a uniform grade for the pipe, the supporting bents varied from a few feet to as much as 50 feet in height.

At all of the developments where a tunnel was required to divert the river during construction, the project has been designed so that this diversion tunnel is subsequently used for carrying the water from the reservoir to the powerhouse. This required that the intake be located at a very low level in the reservoir, and it therefore created considerable pressure on the intake gate. To overcome the difficulty of raising such a gate against pressure, filler valves were built into the face of some of the intake gates for filling the tunnel or pipe line to equalize the pressure before the gate is opened. This filler valve is moved by the same cable that operates the gate and therefore automatically opens first and closes last.

Tunnels are unlined except for short lengths at the intakes, at the downstream ends, and at a few locations where bad ground was encountered. It is more economical to drive the tunnels to a large section, permitting truck haulage and keeping water velocities low, than to drive small sections giving higher velocities and requiring lining. There are no inlet valves at the powerhouses at Tuckasegee, Cedar Cliff, and Bear Creek, and unwatering for maintenance is accomplished satisfactorily by use of the intake gates. No surge tanks or pressure relief valves are used at Cedar Cliff or Bear Creek even though the conduit lengths are 1,152 feet and 1,484 feet respectively. Effective control of speed and pressure rises is maintained by the governors.

Considerable savings in initial construction costs of many of these projects has been realized by designing the controlled spillway structures, such as taintor gates, to pass flows of 25 to 50-year flood magnitude with relatively inexpensive washout-type fuse plugs for larger, less frequent flows. Before the fuse plugs would be washed out, the flood flow would have reached such magnitude that the additional discharge from the lake storage through the fuse plugs would not contribute excessively to the flood peaks downstream. These fuse plugs are usually earth fills that are easily replaced when and if they are washed out.

Rock Fill Dam

The development of the rock fill dam has probably been the greatest factor in reducing construction costs of small hydroelectric projects. On small streams where the flood flows can be passed around the dam through low saddles between adjoining hills or through spillway and cascade sections cut into the rock abutments at the ends of the dam, the rock fill type of construction provides a very economical structure which in many cases costs less than one-third as much as a concrete structure.

The reason for the reduced cost is fundamental and very obvious. Rock can be quarried from the spillway and cascade area and placed in the dam for about $1.50 per cubic yard, whereas concrete would cost about $20.00 per cubic yard, depending on the availability of cement and suitable concrete aggregate. Thus, per cubic yard, the rock fill costs less than one-twelfth as much as concrete, and since the rock fill requires only about four times as much yardage as a gravity concrete dam, the economy of the rock fill dam is evident. Company studies indicate that concrete can be justified only at locations that lend themselves perfectly to a thin section arch dam. Even in such cases, the rock fill would usually be competitive.

There are many additional advantages that the rock fill construction possesses:

1. The rock fill dam can be constructed on foundations that are completely unsuitable for concrete structures. Unit loads are much less and foundation conditions less critical, thus permitting a wider choice of site and reduction of foundation treatment.

Fig. 1. Single-line a-c schematic diagram of the Bear Creek project

2. The rock fill dam of the earth-faced type is practically immune to damage by earthquakes or sabotage. The elasticity of the impervious clay fill makes it self-healing and it actually tightens and improves with age. Leakage is therefore held to a minimum. One engineer has estimated the life at one million years and states that after that he is not concerned about what happens to the structure.

3. Construction of a rock fill dam does not require much equipment other than the road building type, and requires very little high cost, expert supervision, control, and inspection, which means that more contractors are qualified to perform the work. Design costs are also less than for concrete structures.

4. The material for a rock fill dam is practically always available at the site in mountainous regions. The quality of rock is not critical since the design can be modified to use almost any type of rock and earth that is available. There are never any national emergency restrictions on the use of rock and earth such as often exist for cement and reinforcing steel.

5. Loads and stresses in the dam and foundation are low and free from abrupt changes. The water load is carried into the foundation directly by the shortest path, thus eliminating stability problems.

6. Danger from uplift is eliminated by the free draining rock fill.

The Bear Creek Development

The Bear Creek development is typical of several of the projects that have been

Table I. Summary of Pertinent Data on Five Projects Completed Since 1948 or now Under Construction

Name of Project	Queens Creek	Tuckasegee	Cedar Cliff	Bear Creek	Tennessee Creek
Size of unit, kva	1,800	3,333	7,500	10,000	12,000
Average net head on unit, feet	929	117	169	224	486
Average annual generation, megawatt-hours	5,000	13,200	24,300	32,400	40,700
Drainage area, square miles	3.6	54.7	80.7	75.3	40.1

Height of dam, feet	78	61	165	215	180 and 140
Cost per installed kilowatts, dollars	310	300	220	280	350*

*This project also provides storage benefiting downstream plants.

designed and constructed in recent years. It is the middle of a series of three dams which develop most of the hydroelectric potential of the East Fork of the Tuckasegee River in Jackson County, N. C. Above this dam site, there are 75.3 square miles of drainage area which provide an average runoff of 225 cubic feet per second.

The dam is approximately 215 feet high, 750 feet long, and the quantities measured as placed include about 850,000 cubic yards of rock, 70,000 cubic yards of filter material, and 165,000 cubic yards of impervious clay fill. It creates a reservoir with a useful storage of 2,287 day-second-feet.

Additional storage is provided by an upstream development so that by utilizing the smaller storage on this stream with the much larger storage capacity of a development on the West Fork of the Tuckasegee River the daily and seasonal variations in stream flow can be effectively regulated to provide a satisfactory output throughout the year. The spillway and cascades were cut through rock on the right abutment of the dam; the volume of these excavations was designed to provide the required amount of rock for the dam and actually an almost perfect balance was obtained in construction with no rock wasted other than a relatively small amount of unsuitable decomposed rock that was taken out of one of the cascade sections. The spillway includes one electrically operated taintor gate which will pass approximately 10,000 cubic feet per second. A washout type of fuse plug is installed between the taintor gate and the abutment of the dam to pass an additional 50,000 cubic feet per second in the event of extreme floods. All of this flood water is discharged around the dam over cascades that are cut into the solid rock abutment. The initial coffer-dam serves as a portion of the completed structure of the dam. The main portion of the dam was constructed in three lifts. The first stage was the placement of the upstream rock toe to elevation 2,435, following which the filter material, impervious and upstream rock blanket were all completed to the same elevation. This, in effect, allowed work to be completed in the seal trench at approximate elevation 2,360 in the river bed at an early date and as the fill increased in height provided additional insurance against overtopping of the coffer-dam by floods. During the second stage of construction, the rock was dumped from elevation 2,540 across the entire length of the dam, following which the filter material, impervious and upstream blanket were competed to this elevation. The final stage involved the construction of the crown from elevation 2,540 to elevation 2,580. In this section all material was brought up simultaneously.

The turbine, rated 13,000 horsepower, at 230-foot head, drives a 10,000-kva generator at 90-per-cent power factor, 4,160 volts, 400 rpm. The powerhouse is only 30 feet 6 inches by 40 feet 9 inches, yet it contains all the necessary equipment, including switchgear and switchboards, with enough storage space for the generator rotor. Of particular interest might be the method of cooling the generator which provides for the admission of outside air through a 6-foot by 6-foot inlet damper near the top of the powerhouse wall with the discharge of hot air from the generator through an opening below the generator floor level. By-pass dampers are used to warm the powerhouse during cold weather.

The switchyard is located immediately adjacent to the powerhouse and consists of a small steel structure 16 feet by 20 feet in plan. In order to save space, substation steel, and 66-kv bus, two circuits have been arranged vertically entering the station on the same bay. A motor-operated air-break switch provides for sectionalizing the transmission line which extends to the Tennessee Creek project approximately 4 miles upstream. A single-pole grounding switch and 3-pole motor-operated air-break switch are installed for protection of the Bear Creek transformer.

Fig. 1 is a single-line a-c schematic diagram of the station. Most of this arrangement is conventional except, as explained in a previous paragraph, for the differential protection of the generator, protection of the transformer bank, and use of station service supply for synchronizing potential. The relaying, supervisory, and telemetering equipment has been kept to the minimum that was considered practical to provide adequate protection and satisfactory control from the remote attended station. Table I summarizes data on five projects from 1948 to the present.

Vibration in 2-Pole Induction Motors Related to Slip Frequency

ERNEST W. SUMMERS
ASSOCIATE MEMBER AIEE

VIBRATION and noise in a 3-phase 2-pole a-c motor quite often are characterized by a pulsation or beat in the amplitude, i.e., the amplitude of the vibration and noise increases and decreases at a uniform frequency which is related to the slip of the rotor. In many applications, these pulsations are not detrimental to the performance of the machine, but they have an adverse psychological effect upon anyone in the vicinity of the machine because a noise which pulsates is much more noticeable than one which is steady. Performance can be influenced in applications where an a-c motor is built into a common frame with another machine such as a d-c generator. With this construction, the pulsations can cause a variation in commutation or in the generator output voltage.

Vibrational pulsations of this nature encountered in 2-pole motors are of the order of from 1/2 to 10 cycles per second (cps) depending upon the slip of the rotor and the type of pulsation. A normal human ear cannot hear vibrations much under 15 cps, but these pulsations are definitely audible. Therefore, it is reasoned that the pulsations are not a single fundamental frequency but must be the result of co-operation between two different frequencies at least one of which is in the audible range.

Two types of pulsations are encountered most frequently. The most common one varies at two times slip frequency, and the second varies directly with slip. The purpose of this paper is to describe the fundamental conditions which must exist to produce pulsations of the nature described and how in 2-pole a-c motors certain mechanical and electrical dissymmetries co-operate to produce vibrational driving forces which meet these conditions.

The conclusion is reached that a perfectly symmetrical machine will not have vibrational pulsations, and that to minimize the driving forces all parts of the machine must be made as symmetrical as practical both mechanically and electrically. Also, to minimize the response to the driving forces, the natural frequency of all parts of the machine must be kept away from running frequency and twice line frequency.

The Nature of Low-Frequency Pulsations

Fundamentally, low-frequency pulsations in electric motors can be caused in two different ways. First, the amplitude of a given vibrational force wave may be modulated by another vibrational force which has a frequency different from that of the first. A typical fully modulated wave is shown in Fig. 1. Here, the carrier frequency wave is modulated by a wave which has a relatively low frequency. The amplitude of the carrier wave increases and decreases uniformly or pulsates as dictated by the modulating wave, but its frequency remains constant. The general equation for a sinusoidally modulated wave is

$$a=(A_0+B_m \sin \omega_1 t) \sin \omega t \qquad (1)$$

where

A_0 = maximum amplitude of unmodulated wave
B_m = maximum amplitude of modulating wave
ω_1 = modulating frequency
ω = carrier frequency

Second, if two vibrational driving forces exist simultaneously having approximately the same frequency, they alternately aid and buck one another causing the phenomenon of beats. The frequency of the beat or pulastion is the difference between the two frequencies. Since the addition of two sine waves of slightly different frequency does not produce the same curve as when two sine waves are multiplied, the resultant wave will not look exactly the same as the modulated wave in Fig. 1, but the envelope of the amplitude will have precisely the same characteristic. Thus, it is impossible to listen to a machine and determine whether a pulsation is the result of a modulation or a beat.

Two Times Slip Frequency Pulsations

In any 2-pole a-c machine, many vibrational driving forces, both mechanical and electromagnetic, exist simultaneously and can co-operate to produce both phenomena just described. Assume a motor which is perfectly symmetrical mechanically. The radial magnetic force between the rotor and stator core at each of the magnetic poles tends to distort the core periodically as the magnetic field rotates. Since a force of attraction exists regardless of the polarity of the pole, a vibrational force of twice line frequency always results. This second harmonic driving force is independent of the number of poles, but is more prominent in 2-pole machines because the distance between poles is relatively greater. Now consider a 2-pole machine in which the center of rotation of the rotor coincides with the center of the stator, but in which the rotor is not round. This means that there is a point of minimum air gap which travels at rotor speed. In a 60-cycle 2-pole machine, the revolving field rotates at a speed of 60 revolutions per second (rps), or 3,600 rpm. If it is assumed that the rotor speed is 59 rps, and that the point of minimum air gap starts at time zero in the center of the north pole, then, when the north pole has made on revolution, the point on the rotor will have made 59/60 of a revolution. The rotor will keep falling behind and when the field has made 30 revolutions, the point on the rotor will have made 29.5 revolutions and so will line up with the south pole. When the field has made 60 revolutions, the rotor will have made 59, and the point will coincide with the north pole again. Thus, in 1 revolution of slip, the point of minimum air gap has come under the influence of maximum flux density twice

Paper 55-133, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 21, 1954; made available for printing December 8, 1954.

Ernest W. Summers is with the Westinghouse Electric Corporation, Buffalo, N. Y.

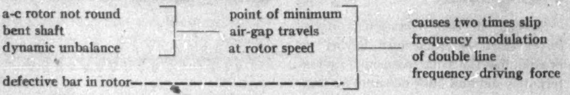
The author sincerely appreciates the guidance and advice given to him by his associates, particularly H. C. Werner.

and, therefore, the frequency of the unbalanced magnetic pull between the rotor and stator is twice slip frequency. This vibrational driving force is superimposed on the normal twice line frequency driving force and modulates it at twice slip frequency.

A revolving point of minimum air gap can be caused by other dissymmetries such as a bent shaft, or dynamic unbalance combined with a weak shaft. With dynamic unbalance, the geometrical center of the rotor does not coincide with the axis of rotation but lies on a circle about this axis. The diameter of this circle depends upon the amount of unbalance and the stiffness of the shaft.

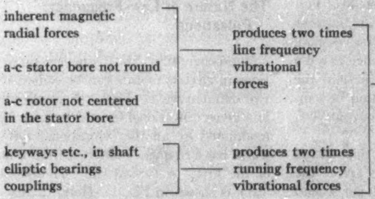
Electrical dissymmetries in the rotor such as a defective bar will also cause modulation. This can be explained briefly in the following manner. Normally the ampere-turns of the stator and rotor tend to balance one another except for the excitation ampere-turns. If it is assumed, however, that a rotor bar is open circuited, then the current flowing in it and, thus, the ampere-turns produced will be greatly reduced. The net unbalanced stator ampere-turns will produce an air-gap flux density greater than normal at the point of the defective bar. This increased flux density will cause a higher induced voltage and, thus, a higher current in the bars adjacent to the defective bar; hence the net effect is that the stator and rotor ampere-turns still balance one another, but the flux distribution in the air gap is altered. This change in flux distribution is most pronounced when the defective bar is under a magnetic pole and least effective when it is between poles. Since the defective bar is passed by a magnetic pole twice for each revolution of slip, the inherent twice line frequency vibration is modulated at two times slip frequency. Obviously, the motor torque will also pulsate at this same frequency.

Pulsations caused by modulation can be summarized as follows:



Consider next the vibrational forces that contribute to the phenomenon of beats.[1] In addition to the inherent twice line frequency vibrations mentioned previously, certain mechanical dissymmetries will also cause twice line frequency driving forces. Assume that the center of rotation of the rotor coincides with the center of the stator and that the rotor is round, but the stator is slightly elliptical. As the field rotates, it passes a point of minimum air gap twice each revolution and, thus, produces a vibrational force of twice line frequency. If the rotor and stator are both round but the rotor is not perfectly centered in the stator, the same frequency vibration results.

Several mechanical driving forces exist which can cause two times running frequency vibrations. A shaft which has noncircular cross sections, caused by keyways for example, or elliptic bearings are the two most important examples.[2] This second harmonic driving force is not particularly important except in 2-pole machines in which the harmonic differs from twice line frequency by two times slip frequency. Thus, these two driving forces alternately reinforce and interfere with each other and produce a beat. The conditions producing this beat can be summarized as follows:



Another factor which must be included when considering the causes of the beat phenomenon is the space harmonics in the main flux wave.[3] Parasitic torques will be produced by these harmonics, but they also produce parasitic radial forces which tend to cause noise and vibration. As an example, consider the stator 5th harmonic which travels around the stator in the direction opposite to that of the fundamental. The 5th harmonic has five times as many poles as the fundamental, or ten poles. The time variation of all the stator harmonics in the air-gap flux is the same as for the fundamental since they are all produced by the same current. Therefore, with sinusoidal impressed voltages, the revolving harmonic component fields in the air-gap flux caused by the windings revolve more slowly than the fundamental field. Thus, the 5th harmonic revolves one-fifth as fast as the fundamental, or 12 rps for a 60-cycle 2-pole machine. With ten poles revolving at 12 rps, a vibrational driving force of 120 cps is produced which is exactly the same as the fundamental. In the same manner it can be shown that all of the stator harmonics will produce radial forces of twice line frequency. This is one reason why they make the pulsation worse.

There is, however, a more important aspect of the situation. The frequency of the voltage induced in the rotor by a space harmonic is equal to the line frequency times the slip of the rotor with respect to the harmonic.[4] In the Appendix it is shown that for the 5th harmonic which rotates in the opposite direction of the fundamental

$$f_2 = f_1(6 - 5S_1) \tag{2}$$

where

f_1 = frequency of the fundamental
S_1 = slip of the rotor with respect to the fundamental

For the 7th harmonic, which travels in the same direction as the fundamental

$$f_2 = f_1(-6 + 7S_1) \tag{3}$$

If a slip of 5 per cent or 3 rps for a 60-cycle 2-pole machine is assumed, the frequency induced by the 5th harmonic in the rotor is

$$f_2 = (60)(6 - 5 \times 0.05) = 345 \text{ cps}$$

The frequency induced by the 7th harmonic is

$$f_2 = (60)(-6 + 7 \times 0.05) = -339 \text{ cps}$$

Numerically, these two frequencies differ by 6 cps, or two times slip frequency. The negative sign for the 7th harmonic merely means that its motion relative to the rotor is opposite that of the 5th harmonic. Thus a point on the rotor sees two revolving fields which are aiding one another when they are in phase and bucking when they are out of phase. The net result is that a torque pulsation occurs which varies at two times slip frequency. Other harmonics such as the 11th and

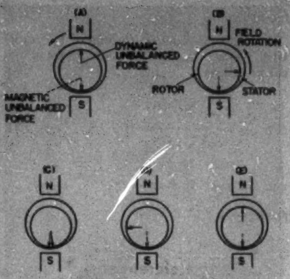


Fig. 2. Dynamic unbalance modulated by magnetic unbalance

13th, 17th and 19th, 23rd and 25th, etc., also beat with one another at the same frequency.

It is well known that the magnitude of the space harmonics can be suppressed by the proper winding pitch. The most desirable pitch is 83 per cent which reduces the 5th and 7th harmonics to about 26 per cent of that with full pitch. Since small 2-pole machines are very difficult to wind with this long a throw, the best compromise is 55 to 57 per cent which reduces the 7th harmonic to a small value. It is important to note that, if the winding is such that prominent space harmonics are present, the pulsation can occur even if the rotor, stator, and air gaps are perfect.

Pulsations Which Vary Directly with Slip or as a More Complex Function

Certain combinations of mechanical and electromagnetic forces can cause other pulsations which vary with slip. For example, assume that the rotor is dynamically unbalanced and that it is not perfectly centered in the stator, as shown in Fig. 2. When a magnetic pole (either north or south) lines up with the minimum air-gap point and the mechanical unbalance vector is 180 degrees from this point, the unbalanced magnetic pull will tend to reduce the mechanical unbalance. Assume again that the field rotates at 60 rps and the rotor at 59 rps. When the field has made 15 revolutions, the rotor will have made 14.75 revolutions, or will have slipped 1/4 revolution, as shown in Fig. 2(B). Later, when the field has made 30 revolutions and the rotor 29.5, the mechanical unbalance vector lines up with the south pole, as shown in Fig. 2(C), and the two force vectors are in space phase. The rotor keeps slipping further behind until it has slipped 1 full revolution and the mechanical unbalance vector once more lines up with the north pole, as shown in Fig. 2(E).

Note that the magnetic unbalanced force vector remains stationary in space and exists only when a magnetic pole is at the small air gap, while the mechanical unbalanced force vector revolves with the rotor. Thus, the running frequency vibration caused by dynamic unbalance will be modulated by the unbalanced magnetic force. The frequency of the modulation will vary with slip, but is not a continuous function of slip. This modulation requires that a point on the rotor and the revolving field coincide with a point on the stator periodically, and thus it has 1 degree less of freedom than the two times slip frequency modulation. For certain values of slip, the three points may never coincide. Using the same example as previously, if the revolving field has a velocity of 60 rps, and the rotor 59 rps, then a magnetic pole will pass a point on the rotor two times per second. Furthermore, the point on the rotor and magnetic field will always meet at the same points on the stator, and it is possible that none of them are the point of minimum air gap.

This depends on the initial relative position of the three points. If the initial conditions are correct, then the running frequency will be modulated at exactly slip frequency. If not, no modulation, or only slight modulation will occur at slip frequency. With the rotor speed of 49.1 rps, a pole will pass a point on the rotor 1.8 times per second and they will meet at progressively different points on the stator. Thus, the rotor and field may eventually coincide or come close to coinciding with a particular spot on the stator, but the frequency of the modulation will be less than slip frequency. It is difficult to write a mathematical expression to prove this, but a graph which shows the position of a point on the rotor and the magnetic field with respect to the stator at any instant will illustrate it. If several types of dissymmetry are involved, the situation is even more involved. Actually, an arc of the stator should be considered rather than a point because, if the rotor is off center, the gap will be small for an appreciable part of the circumference. For this reason, and the fact that the slip is not absolutely constant, the pulsation is usually slip frequency or close to slip frequency.

Often an a-c motor is combined with a generator in a unit frame 2-bearing set. Some generators such as d-c machines with half as many commutating poles as main poles, and some types of high frequency generators, have a condition where the armature and the frame are at different potentials magnetically. This can cause a d-c flux to flow through the shaft, a-c rotor, air gap, and core and back through the frame to the generator. If the a-c motor were not excited, this flux would be distributed uniformly around the a-c air gap, but with the motor excited it will be concentrated at either the north or south pole depending upon the polarity of the d-c flux. With more than two poles the magnetic attraction between the rotor and stator will remain balanced, but with two poles an unbalanced magnetic force exists because of the difference in flux density in the two diametrically opposite air gaps. This unbalanced force rotates at synchronous speed and thus passes a point on the rotor once for each revolution of slip. Now, if the rotor is dynamically unbalanced, a situation similar to the previous one exists, i.e., the unbalanced magnetic force alternately increases and decreases the amplitude of the running frequency vibration. The frequency of this pulsation is always slip frequency since it is independent of position with respect to the stator. If, in addition, the rotor is not centered in the stator, then the slip frequency pulsation also could be modulated at some lower frequency.

IDENTIFICATION AND ELIMINATION OF PULSATIONS

Whenever a pulsation is encountered, it can be determined which of the two general types it is by accurately measuring the slip and the frequency of pulsation. Further evidence can be obtained by measuring the frequency of the vibrations in the machine. If a prominent vibration of approximately twice line frequency exists, and it pulsates, then it is the first general type. However, if a predominate running frequency vibration exists which pulsates, it is the second general type.

Thus far, only the vibrational driving forces which exist have been considered, but the final amplitude of vibration is dependent upon both the amplitude of the driving forces and the vibrational response of the various parts. Therefore, the pulsations can be eliminated by correcting either or both factors. Once the type of pulsation is determined, changes can be made to minimize the driving forces, listed previously, causing it. It is impossible to eliminate all of the driving forces but, unless the mechanical or electrical dissymmetries are quite large, the forces tending to produce the pulsations will be relatively small and excessive vibration will not occur unless some part of the machine is resonant.

It is very important that the natural frequency of all parts of the machine and particularly the shaft be something other than running frequency or twice line frequency. The shaft frequency can be between the two frequencies, but it would be desirable to have it at least 10 per cent above twice line frequency.

Conclusions

It is obvious from the previous analysis that a perfectly symmetrical 2-pole 3-phase a-c motor would not be afflicted with vibration pulsations, although it still might vibrate. The conclusion is reached that to eliminate vibration pulsations the following things must be done:

1. Make stator bore, air gaps, and rotor as accurate and uniform as practical.
2. Make the shaft straight, without noncircular cross sections, and with perfectly round ball-bearing fits. These factors are of less importance if the natural frequency of the shaft is well removed from twice running frequency.
3. Keep the natural frequency of all parts, but particularly the shaft and stator core, away from running frequency and twice line frequency.
4. Make rotor symmetrical electrically, and use a stator winding pitch which suppresses the space harmonics and particularly either or both the 5th and 7th harmonics.

Appendix. Slip of Rotor with Respect to Harmonics

The slip of the rotor with respect to a stator space harmonic is equal to the difference between the speed of the harmonic field relative to the stator and the speed of the rotor relative to the stator divided by the speed of the harmonic field; thus, the slip of the rotor with respect to the 5th harmonic is

$$S_5=\frac{-\frac{2f_1}{5P_1}-\frac{2f_1}{P_1}(1-S_1)}{-\frac{2f_1}{5P_1}}=6-5S_1 \qquad (4)$$

where

P_1 = number of poles of the fundamental
f_1 and S_1 are as defined previously

The frequency of the voltage induced in the rotor by the 5th harmonic is

$$f_5=f_1(6-5S_1) \qquad (2)$$

In the same manner, the slip of the rotor with respect to the 7th harmonic can be calculated as

$$S_7=\frac{\frac{2f_1}{7P_1}-\frac{2f_1}{P_1}(1-S_1)}{\frac{2f_1}{7P_1}}=-6+7S_1 \qquad (5)$$

and for the 7th harmonic

$$f_7=f_1(-6+7S_1) \qquad (3)$$

Improved Field Conductor Materials for Turbine Generators

C. H. HOLLEY
MEMBER AIEE

R. E. SAVIDGE
NONMEMBER AIEE

THE present demands for large unit ratings in 2-pole high-speed turbine generators have dictated that the field winding conductor materials be unusually strong to withstand the various mechanical stresses applied during the operation of the machine. At the same time, high electrical conductivity must be maintained so that the material can be utilized most efficiently.

Some 10 years ago the General Electric Company embarked on a program to improve existing conductor materials and to develop new alloys, which would provide design engineers with greatly improved conductor materials permitting generator design to keep pace with the industries' demands.

In the past, field conductor distortion was one of the limitations in designing a thoroughly reliable large turbine-generator field. Various authors[1–4] have adequately described the causes of and the difficulties from such conductor distortion, but this problem is again briefly stated for purposes of reference in the following.

Conductor distortion results from a cycle beginning when the generator starts to rotate after a shutdown. At this time, the field conductors, which are cold, are thrown outwards by centrifugal force and being restrained by the wedges gradually become locked in by this force at approximately two-thirds rated speed. When synchronous speed is reached, field current is applied, the generator is connected to the system, and load is picked up. During this increased application of field current, the conductors heat up and attempt to expand. However, since they have previously been locked in, due to the centrifugal force, the thermal expansion is restrained and a resulting compressive stress is applied to the conductors. At these elevated temperatures [hot-spot temperatures may vary from 100 degrees centigrade (C) to 140 C] the compressive stress applied may cause plastic deformation if:

1. The stress exceeds the elastic limit of the material as defined by the compressive stress strain curve at operating temperature.
2. The high loadings obtained at these temperatures exceed the compressive creep strength of the material.

Each of these phenomena may produce a minute but significant upsetting in the conductor material. As this cycle is repeated (i.e., beginning from a cold start) the upsetting is again introduced and the effect is additive.

The results of this conductor distortion,

Paper 55-131, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 19, 1954; made available for printing December 2, 1954.

C. H. Holley and R. E. Savidge are with the General Electric Company, Schenectady, N. Y.

The authors are indebted to many persons both within and without the General Electric Company. Particularly, we gratefully acknowledge the outstanding contributions of L. B. Barker of the General Electric Company and Prof. M. F. Sayre of Union College in the design and operation of the creep testing apparatus and the accumulation of test data. Special acknowledgment is due R. H. Harrington, metallurgical consultant, for his original work on Cond-Al and his guidance during the development of the alloy on a commercial scale. Appreciation is also due H. D. Taylor for his foresight in initiating this program and continued encouragement and guidance and to H. F. McCullough and M. F. Kent for their contribution in the early development stages. Also, thanks are due to J. D. Lubahn and B. M. Cain for their helpful suggestions in the preparation of this paper.

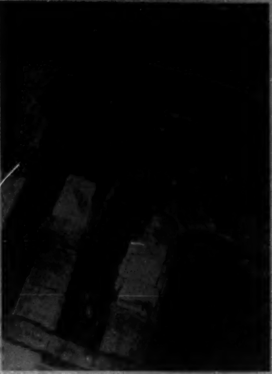

Fig. 1. View of end winding conductor distortion showing lower turns of coils pulled in towards field body

as illustrated in Fig. 1, have been observed on generators built by various manufacturers in this country[4] and in Europe.[1,2] The effect has been pronounced on field windings made with annealed tough-pitch copper and annealed electrical conductivity (E.C.) grade aluminum. The authors' company has approached the distortion problem in three ways:

1. By the development and use of improved conductor materials which have high physical properties and resistance to creep capable of withstanding any stress imposed during the operation and life of a turbine generator.
2. By the design and use of improved field winding ventilation methods which keep both the hot-spot and average field temperature to a minimum and thereby reduce the stress on the conductors due to lower differential expansion and at the same time increase the life and reliability of the insulation.
3. By preheating[4,5] which is an effective preventative of distortion in generator fields.

This paper will deal directly with item 1, i.e., the development and use of superior field conductor materials.

A 2-step development program to produce the required field conductor materials was initiated as follows:

a. An intensive test program to determine the physical properties (including compression creep at elevated stresses and temperatures) of commonly used field conductor metals and those developed under item b.

b. The development of high conductivity copper and aluminum alloys with a compressive yield strength of 12,000 pounds per square inch (psi) or better at 140 C and with negligible creep at this loading and temperature.

The results of this program have been encouraging.

Silver and cadmium bearing coppers are now available and in use that have compressive yield strengths at 140 C of about 20,000 psi, or more than three times that of annealed tough-pitch copper. These alloys undergo less than 2 per cent (%) the amount of deformation in compression creep of annealed tough-pitch copper at stress levels existing in generators with no sacrifice in electrical conductivity.

An aluminum alloy (Cond-Al) is in commercial use which has a compressive yield strength at 140 C of 15,000 psi or about four times that of annealed E.C. aluminum. Cond-Al suffers less than 1% as much deformation in compression creep as annealed E.C. at machine stress levels and 10% the creep of annealed E.C. which has been 20% cold worked and stress relieved. The electrical conductivity of Cond-Al is within 2% of E.C. aluminum.

Test Program

The foregoing analysis of the problem shows that the principal mechanical properties in question are compression yield and creep strengths. It was decided to study creep with the stress applied in compression since this most nearly duplicated the conditions in the generator, and it was desirable to avoid errors due to the Baushinger effect (the phenomenon by which plastic deformation of a metal raises the yield strength in the direction of plastic flow and decreases the yield strength in the opposite direction).

Since no commercial apparatus was available for such tests, a compression creep machine was designed.[6] In this machine the load is applied to the ends of a 1-inch by 5/16-inch by $5^{1}/_{2}$-inch specimen through a yoke arrangement. The specimen is supported on the sides just enough to prevent buckling without producing noticeable friction. Tube and push rod extensometers transmit the changes in the 5-inch gauge length from the sides of the specimen to two dial indicators above, which are graduated in ten-thousandths of an inch. The average of the two readings is used to plot the creep curves. With this equipment, a study of the compression creep properties of the commercially available high conductivity materials was begun immediately. Development alloys were run as soon as they were available.

Copper Program

A review indicated that more favorable results would be expected if the copper were strengthened by using some cold work and with the addition of silver or cadmium to raise the recrystallization (softening) temperature. Five % cold work was established as a reasonable amount for two reasons: 1. the softening temperature decreases with increasing cold work, and 2. springy copper is difficult to assemble during the winding operation. Fig. 2 shows the effect of silver on the annealing temperature of copper.[7] The commercial alloy containing 8 to 10 ounces of silver per ton of copper was chosen because the very large rise in softening temperature in the early part of this curve is adequate for the purpose.

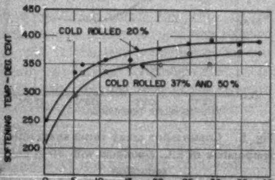

Fig. 2 (left). Effect of silver on softening temperature of copper. Data taken from reference 7

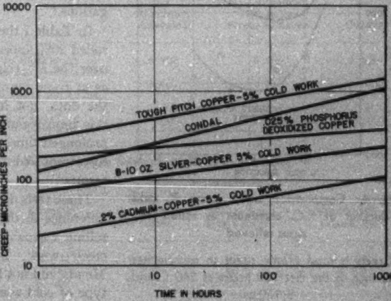

Fig. 3 (right). Compression creep of some coppers and Cond-Al at 140 C (284 F) and 8,000 psi

Table I. Mechanical Properties of Some Coppers

Material		Room Temperature Tensile			140 C—Compression		200 C Tens.

*Annealed at 500 C for 1 hour.

An alloy of copper with 1% cadmium was available but the 87% conductivity of this alloy was too low for this end use. Data prepared by Smart and Smith[8] show that the addition of 0.2% cadmium lowers the conductivity only about 1.5% and increases the softening temperature of tough-pitch copper by 200 C. Tests were made of a copper alloy containing the nominal amount of 0.2% cadmium. There was no reason to suspect that OFHC, phosphorous-deoxidized, or selenium-bearing copper would prove to be any improvement over tough-pitch, but since no data were available these were included in the tests.

Typical creep curves which were obtained for several of the coppers are shown in Fig. 3 and the compiled data for all the coppers tested are shown in Table I. In both comparisons the improvement in creep properties, rupture strength, and softening temperature because of the addition of silver or cadmium is obvious.

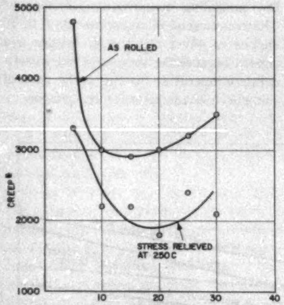

Fig. 4. Compression creep versus % cold reduction of E.C. aluminum as rolled and stress relieved

*Creep is total plastic strain in microinches per inch in the first 100 hours at 140 C and 5,130 psi

The phosphorous-deoxidized copper provides an increase in creep strength, but this high residual phosphorous reduces the electrical conductivity to about 80%. Phosphorous, cadmium, and silver all have the effect of raising the recrystallization temperature of copper.

As was expected, the 0.5% selenium copper alloy was not different from tough-pitch. Selenium has virtually no solid solubility (mixing of solids where the components are atoms) in copper and, consequently, no noticeable effect on the mechanical properties.

This investigation did not show OFHC copper with silver or cadmium to be any better than tough-pitch copper with silver or cadmium. Evidently, the effects of these two addition elements overshadow any effects which might be due to the insoluble oxides of copper. This agrees with the results of other investigations.[9]

In Table I the tough-pitch copper cold rolled 20% appears to be an improvement over the 5% cold rolled at 140 C as well as at room temperature. Other plots of the data, not included here, show that this improvement is not maintained for prolonged times at 140 C. Tensile creep tests reported by others[9] confirm these results.

These tests did not show any significant difference in the creep properties due to rolling versus drawing. In their tension creep work, Benson, McKeown, and Mends[9] did not find any effect due to the type of cold work, and this is again confirmed by our work on aluminum reported later in this paper and by recent work on our aluminum alloy, Cond-Al. It is well known that there will be a considerable difference in the response of copper to cold work due to grain size, minor impurities and their distribution, and alloying elements. Much more extensive work would have to be done to separate these variables before any significant conclusions could be drawn.

Aluminum Program

Aluminum field windings extend the design possibilities in generators by decreasing the load on the retaining rings and rotor forgings and permitting the manufacture of large diameter rotors. Aluminum has about 61% of the volume conductivity and a specific gravity of 31% that of copper so that for equal conductance only 51% as much weight of aluminum is required.

After a considerable number of genera-

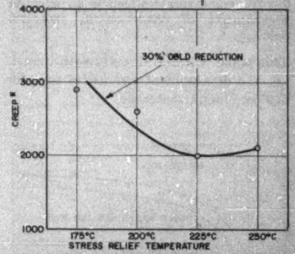

Fig. 5. Compression creep versus stress relief temperature of E.C. aluminum with 30% cold reduction

*Same as Fig. 4

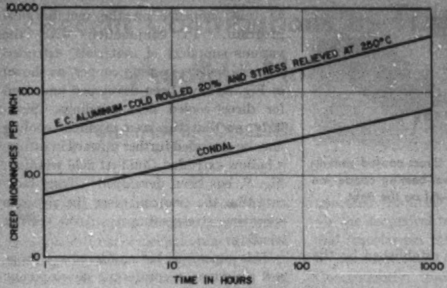

Fig. 6. Compression creep of Cond-Al and E.C. aluminum at 140 C (284 F) and 5,000 psi

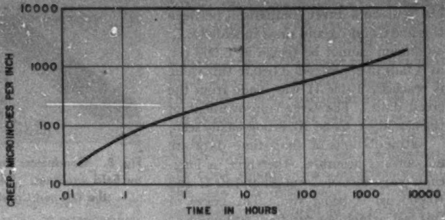

Fig. 7. Compression creep of Cond-Al at 10,000 psi and 140 C

tors had been wound with E.C. grade aluminum, it was found that these windings were susceptible to failure by compression creep, but the advantages of aluminum were so outstanding that work was begun to improve this property in E.C. aluminum. The program to improve the compression creep properties of E.C. aluminum included work on cold drawing, cold rolling, and stress relief treatments. Tests of drawing versus rolling did not show any significant difference, but it was found that E.C. aluminum could be made more creep resistant by alterations in the usual manufacturing cycle. One of the tests is described now.

Six pieces of an annealed bar were cold rolled by different amounts in 5% increments up to 30% reduction. Part of each piece was tested as rolled and part was tested after it was stress relieved at 250 C [482 degrees Fahrenheit (F)] for 5 hours, except the bar which was rolled 30%, from which additional samples were taken and stress relieved at 175 C (347 F), 200 C (392 F), and 225 C (437 F). The results are plotted in Figs. 4 and 5.

These data show that there is an optimum condition for minimum creep in all three cases. This effect was also found by Zschokke[10] in his work on some steels. In the curve for as-rolled material in Fig. 4, the strengthening effect of cold work is noticeable up to 15%. Above this the cold work has lowered the softening temperature so that 140 C is enough to produce softening during the test. In the other curve of specimens stress relieved at 250 C, the test temperature has virtually no further softening effect. The prior softening has lowered the strength and creep resistance of the specimens with greater than 20% cold work, but 250 C is not enough to soften specimens effectively with less than 20% cold work. A stress relief has taken place without appreciable softening and the strengthening effect of the cold work is still in evidence.

This effect of prior annealing is again shown by Fig. 5. It is already established that softening takes place during the test of the 30% cold reduced specimens. The maximum stress relief with minimum softening is represented by the lowest creep in this curve. For stress relief temperatures below 225 C additional softening takes place during testing; above 225 C the alloy is already too soft to give the maximum resistance to compression creep.

Part of the difference in level of the two curves in Fig. 4 is probably due to the Baushinger effect. The specimens have been made weaker in compression by the cold work in the opposite direction and stress relieving nullifies this effect. The rest of the difference must result from the softening during testing of the cold worked specimens.

The program to develop an aluminum alloy with the required properties has been described.[6] Briefly, studies of recrystallization, electrical conductivity, and rupture strength due to single addition metals[11] provided data to make trial alloys. The alloy selected after extensive tests of several compositions is now known as Cond-Al.[12]

Cond-Al is an age-hardenable alloy with the nominal composition of 0.55 iron, 0.33 magnesium, 0.12 silicon, and the remainder aluminum. The processing of Cond-Al follows the sequence of hot rolling, cold drawing, solution heat treatment, cold rolling 10 to 20%, and age hardening. After this, the alloy is ready to be wound into field coils.

The creep qualities of field coils made of Cond-Al can be seen by referring to Fig. 3. At the stress level of 8,000 psi this alloy falls between cold worked tough-pitch and cold worked silver bearing copper. The improvement in compression creep of Cond-Al over the best condition which we were able to produce in E.C. aluminum, as described in Fig. 4, is shown by Fig. 6. The first E.C. aluminum field coils used in generators were made of annealed material. The values for annealed E.C. could not be plotted in Fig. 6 since the creep rate is so fast at 5,000 psi stress that it is impossible to obtain consistent data. It was desira-

Table II. Comparison of Compression Creep Data for Three Aluminums

	E.C. Aluminum Annealed	E.C. Aluminum Cold Rolled Stress Relieved	Cond-Al
Stress for 0.1% creep at 140 C in 1,000 hours, psi	2,000	4,000	8,000
Creep in the first 1,000 hours at 140 C and 5,000 psi in 0.001 inch per inch	failed	4.6	0.6
Creep in the first 1,000 hours at 140 C and 10,000 psi in 0.001 inch per inch	failed	failed	2
Compressive 0.2% yield strength at 140 C	4,000	8,000	15,000

Table III. Tensile and Fatigue Strength of Three Aluminums

Material	Anneal	Tensile Strength, Psi	Yield Strength 0.2% Offset	Elongation, % in 2 inches	Fatigue Strength 500,000,000 Cycles, Psi
Cond-Al	none	22,800	19,300	22.0	12,000
Cond-Al	450 C	13,250	3,360	43.0	8,400
E.C. Aluminum	350 C	10,800	2,520	58.0	3,300

ble to make a direct comparison between this and Cond-Al, and since annealed E.C. aluminum cannot be tested at 5,000 psi, as it fails in compression before this value is reached, Table II was made from the creep data. The large improvement of the new alloy, Cond-Al, is now easily seen.

Extrapolations of short-time data are not always accurate; therefore, a long-time creep test of Cond-Al at 140 C and 10,000 psi is being run. The curve of this test which has run for 5,600 hours at the time of this writing, is shown in Fig. 7. The creep rate in microinches per inch per hour which is still diminishing was 1.2 at 100 hours, 0.39 at 1,000 hours, and 0.14 at 5,000 hours. A failure such as occurs in tensile creep would never be expected in this test since the specimen becomes larger in cross section and the stress decreases.

In addition to creep, generator windings may also be subject to fatigue stresses; therefore, this property was measured in Cond-Al and annealed E.C. aluminum. These results are shown in Table III. Annealed properties were measured because part of the end of the field coil is softened so that it can be formed to the shape of the rotor during the winding operation. Here again the tests show that Cond-Al is superior.

The electrical conductivity of Cond-Al is 59% International Annealed Copper Standard. The temperature coefficient of resistance of Cond-Al was found to be the same as copper, 0.00385 ohm per ohm per C between 25 and 144 C. The coefficient of linear thermal expansion is 13.1 $\times 10^{-6}$ between 68 and 212 F.

Discussion

Silver-bearing copper has been used in turbine-generator field windings for approximately 15 years. The addition of the silver has raised the recrystallization or softening temperature so that the increased creep strength, due to the previously mentioned cold reduction, is maintained at temperatures above those encountered in service. The silver-bearing alloy also has increased the rupture strength and has eliminated various types of cracking, which have been found on old machines originally wound with annealed tough-pitch copper. Thus the silver-bearing copper has enabled the generator designer to create generator fields which are limited in diameter only by stress limitations on the steel rotor forging and retaining rings, and in length by such considerations as static deflection and critical speeds as established by the bearing spans.

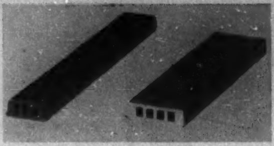

Fig. 8. Conductors for direct-cooled generator field windings. Silver-bearing copper on the left and Cond-Al on the right

The use of cadmium copper has been limited principally because of the restricted supply and higher cost. Its slightly better physical properties have made it attractive for use as amortisseur windings on large special turbine generators for such application as single-phase loading. Cadmium copper, because of its higher recrystallization temperature than silver-bearing copper, stands ready for use as field winding material when new high temperature field winding insulations, which are now being developed, are applied.

Of the various aluminum alloys so far developed, the one that stands out for this application is Cond-Al. To date, there are 31 generators running with Cond-Al field windings with an additional 20 generator fields shipped or on order. The oldest Cond-Al winding from the point of service has been operating for over 5 years. Cond-Al has been used widely in the replacement of original soft E.C. aluminum windings, some of which have been in service for 16 years, but principally it has permitted the extension of generator capability approximately 20% higher than that possible with copper windings, while maintaining conventional insulation and ventilation methods. Cond-Al, with its weight-to-conductivity ratio advantage over copper of almost 2 to 1, permits the design of larger diameter generator fields within the stress limitations on the steel retaining parts than have been possible with copper.

Cond-Al has not been used as a substitute for copper windings but has been used principally to permit the design and use of machines which were not possible with copper. However, the availability on a commercial scale of this new alloy has provided a worthy backup material should copper again become unavailable or in short supply for defense reasons.

The advent of direct-cooling[13,14] of generator stators and rotors has also had a great influence on the metallurgical program. In conjunction with the various suppliers of materials, extruded shapes of silver-bearing copper, as shown in Fig. 8, have been developed and used for direct-cooled field windings. Similarly, so that the area of direct cooling may be extended further upward in rating, a hollow extruded Cond-Al field winding, Fig. 8, has been developed. Tests indicate that the two can meet the rigorous operating stresses impressed on such a winding.

This paper may be considered as a progress report on a continuing development program. Further improvements and new alloys in both copper and aluminum are now being pursued.

Recent Contributions to Transformer Audible Noise Control

WILLIAM B. CONOVER
MEMBER AIEE

ROBERT J. RINGLEE
NONMEMBER AIEE

AUDIBLE noise from transformers has harassed electric power companies and transformer manufacturers for the last decade. Measures to reduce sound levels are expensive at best, and because of the subjective nature of noise it is often difficult to foresee a noise problem when a particular transformer installation is in the planning stage. This has necessitated corrective measures after the transformer is in service, a situation which naturally complicates their application.

Two solutions to the problem are currently being sought by manufacturers. The first approach is to reduce noise at the source by advanced transformer design. This is a long-term development, involving basic metallurgical, structural and electrical factors, some of which are scarcely beyond the research stage. The pieces of this puzzle are slowly and painstakingly being put into place. The second approach is the development of expedients which can provide immediate relief for utilities that have, or foresee the possibility of having, a critical noise problem. This paper deals with two methods which fall in the second category.

The first part will present recently acquired information on the behavior of roofless wall-type barriers. The utility of such barriers lies in their ability to give a fairly substantial reduction in noise level over a wide area, at a cost which is moderate compared to other methods of equal effectiveness. The design of such barriers—and possibly even the decision to use them—is often based on information derived from tests on a model of the specific installation.[1]

The second part of this paper deals with the cancellation of transformer noise by injecting an equal and opposite noise into the troublesome area. This is a new development which has not yet been put to the ultimate test of continuous service in the field. However, it promises to be by far the most economical and satisfactory solution for noise problems where a limited area only is involved.

The full realization of the potentialities of the barrier method, and the rapid perfection of the sound cancellation method, are assured by the availability of an anechoic chamber[2] specifically designed for the acoustical testing of transformers and transformer models. Until recently no adequate facility of this type existed. Consequently, some types of much-needed experimental work were not at all feasible, and other work had to be conducted under conditions which drastically impaired speed and accuracy.

Use of Models to Study Transformer Noise Patterns and Effects of External Barriers

Scale model transformers have been used to study the effects of external barriers on transformer noise patterns.[1] Small speakers housed in a paper enclosure were used to represent the transformer. For the studies reported here, a dynamically scaled transformer core, winding, and tank were used to provide the noise source. In Appendix I the requirements for scaling structures such as transformers have been considered in more detail. The requirements are easily met for structures with little damping by constructing exact scale models.

Models of transformers were constructed to a one-seventh linear scale. To maintain dynamic similarity to the prototype, the model is excited at a frequency of 420 cycles per second (cps), or seven times normal 60-cps excitation. The models were noise-tested to establish:

1. Noise versus distance data for transformer tanks.
2. Polar noise plots; i.e., variation of noise amplitude with azimuth angle.
3. Evaluation of the effect of external barriers upon reducing audible noise.

All measurements were made on the fundamental harmonic of transformer noise.

NOISE VERSUS DISTANCE DATA

The diminishing of noise pressure level with radial distance from the center of the tank has been plotted in Fig. 1 for models of a 125,000-kva transformer and 1,500-kva transformer. Notice that at distances far from the transformers the change in noise pressure level closely follows the square law; i.e., a 6-decibel (db) reduction with each doubling of distance. Each point plotted on Fig. 1 is the average of 20 or more measurements made about the transformer tank. Near the source, along particular radial lines, the change of pressure with distance may be greater or less than predicted by the square law. However, on the average, the noise diminishes in accordance with this law. A discussion of this phenomenon is presented in Appendixes II and III.

VARIATION OF NOISE ABOUT TRANSFORMER

Polar plots of transformer noise as a function of polar angle about the tank indicate that the source is very complicated. The complexity is very probably caused by the involved vibration modes present in the transformer tank. The fundamental and low order modes of vibration of the tank are better radiators of sound than the high order modes when compared on an equal velocity basis. The ability of the low order modes to radiate more noise for a given vibration velocity is offset by the higher velocities present in the modes that are resonant near the transformer driving frequencies. For liquid-filled power transformer tanks, the resonant frequency of the fundamental mode has been observed to be the order of 20 cps or less. For modes resonant near 120 cps, the mode spacing is the order of 20 inches by 20 inches as shown in Fig. 2. Thus, across the length the height of a small power transformer tank, several node lines may be observed for the fundamental harmonic of transformer noise. This subject is treated in more detail in Appendixes III and V. The radiation from several modes is considered in Appendix III and the node spacings for rectangular mode patterns in oil-backed plate are considered in Appendix V.

Probably because of the resonance phenomenon, the noise pattern about

Paper 55-31, recommended by the AIEE Transformers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 25, 1954; made available for printing November 16, 1954.

WILLIAM B. CONOVER and ROBERT J. RINGLEE are with the General Electric Company, Pittsfield, Mass.

The authors are grateful for the many contributions to this work by their associates. Much credit is due to M. W. Schulz for analytical studies which helped form the concepts discussed in this paper. The early success of the sound cancellation experiments is due to valuable ideas by W. F. M. Gray, who also contributed much in the way of equipment construction and field tests. Model barrier and cancellation tests were supervised by K. A. Johnson whose many contributions are appreciated.

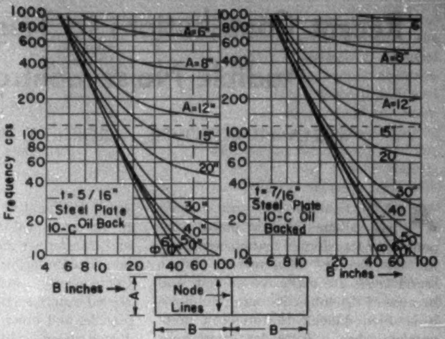

Fig. 2. Resonant frequency curves for rectangular node patterns for a steel plate with 10-C oil on one side and air on the opposite side. System is assumed infinite in extent

the transformer is subject to considerable variation, as much as 30 db for the 125,000-kva model. One might expect that the noise pattern would exhibit a 4-node or cos 2φ shape with azimuth angle φ, but the patterns as shown in Figs. 3 and 4 for the 125,000-kva model and Figs. 5 and 6 for the 1,500-kva model do not exhibit this form. The important consideration to be gained from these data is that the noise patterns about the transformer tanks are directional, being in general higher on the ends of the tank than on the sides. This means that average values of noise as determined by National Electrical Manufacturers Association (NEMA) measurement standards must be treated as the average of a pattern containing several lobes.

While the data presented in Figs 3 through 6 are for the fundamental harmonic of transformer noise, patterns of the same complexity are observed for the other frequency components of transformer noise. Test data taken at scaled heights of 7 feet and 21 feet above ground indicate that the pattern varies with elevation.

External Barrier Tests with Model Transformers

Scale models were chosen for external barrier studies because of the relative ease of construction, ease of changing barriers, and ease of making measurements. The effects of external barriers have been discussed in other papers.[1,3–7] The purpose of the tests was to study the effects of barrier shape and size upon sound attenuation. The effect of barrier height, spacing from the tank wall, and the effect of noise build-up within a hard walled cell were investigated. Tests were made upon 4-sided, 3-sided, and 2-sided enclosures.

The effectiveness of an external barrier is dependent upon three factors: the transmission loss through the wall, the transmission loss due to diffraction around the top and side edges of the walls, and the noise pressure build-up within the enclosure. It is assumed that the wall vibration due to ground-borne motion is small.

The acoustic transmission loss through various wall materials has been studied by the National Bureau of Standards.[8] Choice of a material for a wall should be governed by the amount of noise attenuation needed. As a rough rule, the acoustic transmission loss through the wall material should be at least 10 db greater than the noise attenuation required of the enclosure. It is also essential that wall resonance be avoided at the desired frequencies. Interior grade plywood 3/4 inch thick was used for the model enclosures. The acoustic transmission loss through this material at 840 cps is greater than 25 db.

The pressure build-up within an en-

closure represents the pressure gradients required to decelerate the air motion at the barrier wall. Another way to look at the phenomenon is to consider the multiple reflections of pressure from the hard surfaces of the walls and tank. The vibration of a transformer tank is affected negligibly by the acoustic load imposed by the air about the tank. Pressure build-up can represent a loss in possible noise reduction due to the enclosure. The increased pressure level is equivalent to a source of higher noise level.

Pressure build-up is a function of the spacing of the wall from the tank. Data upon pressure build-up are included with the barrier noise attenuation data in Figs. 7, 8, and 9 and in Tables I and II. For 4-sided enclosures, the build-up ranged from 3 to 6 db; for 3-sided enclosures, from $2^1/_2$ to 4 db; and for 2-sided enclosures, from 1/2 to 4 db.

Pressure build-up data reported were obtained by comparing noise measurements at 1-foot distance to scale from the model tanks at one-third and two-thirds tank height (NEMA test) with and without the enclosures about the tanks. Measurements were taken at 34 microphone positions about the 125,000-kva model tank, and 20 about the 1,500-kva tank, to determine each NEMA average. The data indicated that the build-up was not dependent upon barrier wall height in the range 0 to 10 feet to scale above the transformer cover. The build-ups measured for the three heights 0, 5, and 10 feet were averaged and plotted as a single point.

The pressure build-up inside the model enclosure was reduced to 0 by lining the interior of the enclosure with an acoustic treatment. A 1-inch-thick layer of *PF 615* Fiberglas spaced $1^3/_4$ inches from the wall was used as the acoustic treatment for the model. To scale, this acoustic treatment would have been equivalent to a glass wool blanket in the order of 7 inches thick spaced 1 foot from the full-scale wall. While transformer tanks and barrier walls can be scaled, it is not known if absorption coefficients for glass wools can be maintained as the scale and frequency are changed.

Test data upon 4-sided enclosures showed that the build-up increased as the spacing between the wall and tank was decreased from 11 to $4^1/_2$ feet to scale. These data are presented in Fig. 7. The high build-up experienced at the $4^1/_2$-foot spacing was probably due to the proximity of the spacing to one-half wave length of the sound. One-half wave length of 120-cps sound is 4.71 feet for a sonic velocity of 1,130 feet per second. The air loading upon the tank has negligible effect upon the tank vibration. The tank behaves as a constant displacement source so the sound pressure should increase as the wall spacing approaches $\lambda/2$.

The attenuation of sound by partial enclosures is analogous to the attenuation of light by diffraction over a knife edge. Using this analogy Fehr and Wells have presented a theoretical method for calculating the attenuation of the sound due a point or a line source by a wall. They have presented the theoretical results in curve form[9,10] which gives the attenuation in db as a function of the dimensionless parameter n. The parameter is dependent upon the height of the wall relative to the source, the height of the observer relative to the source, the spacing of the source from the wall, the spacing of the observer from the wall, and the wave length of the sound. Let R be the average distance of the wall from the source, let h be the height of the barrier above the source, and let λ be the wave length of the sound. If the observer and the source are at the same elevation, then at large distances from the source and wall the value of n may be calculated from the relation $n=h^2/\lambda R$, provided $D \gg R$ and $R \geqslant h$. D is the spacing from the wall to the observer.

The simplicity of this method for calculating sound attenuation recommends it as a means for estimating the effects of partial enclosures. Several assumptions are required to apply the theory to a transformer enclosure. The first assumption regards the source. The vibrating transformer tank is assumed to be replaced by a point source located at the geometric center of the tank. The second assumption concerns the interaction of the barrier wall upon the sound within the enclosure. To account for the effect of an acoustically hard wall upon the sound produced by the transformer, it is assumed that the magnitude of the point source is increased by the amount of the build-up. This assumption was confirmed in the tests reported in Tables I and II. The third assumption concerns the method for calculating the distance from the equivalent point source to the barrier wall. For the data reported here, the value of R was determined from an average of the distances from the tank center to the barrier measured to a side wall, to an end wall, and along the diagonal to the corner formed by the side and end wall. For all the tests reported, the spacing S between the barrier and the tank was kept uniform for the side and the end of the tank; see the sketch in Fig. 8.

The test data taken were plotted against the parameter n in Figs. 7, 8, and 9 for 4-, 3-, and 2-side partial enclosures. The value of n for each test condition was calculated in accordance with the three

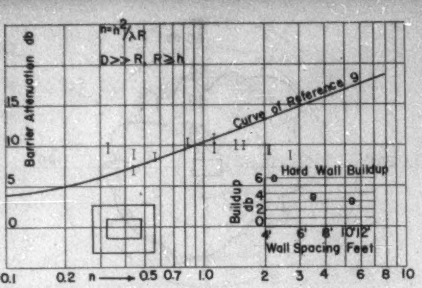

Fig. 7. Four-wall enclosure sound barrier test data obtained with transformer models

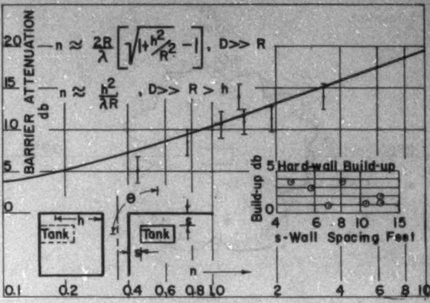

Fig. 9 (above). Two-wall enclosure sound barrier test data obtained with transformer models

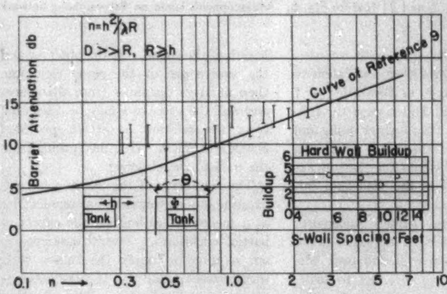

Fig. 8. Three-wall enclosure sound barrier test data obtained with transformer models

assumptions presented. The sound attenuation due to a barrier was determined by comparison of pressure measurements at 42, 84, and 140 feet to scale from the center of the tank before and after the barrier was put in place. Scaled microphone height was 7 feet above the ground plane. The attenuations reported have been corrected for the build-up within the enclosure. The actual or net attentuation is the difference of the attenuation reported and the pressure build-up reported for each barrier configuration. For example, a barrier with a reported attenuation of 10 db and a build-up of 3 db would have a net attenuation of 7/ db. A good acoustic treatment on the barrier wall would reduce the build-up to 0. The corresponding net attenuation would then be 10 db. The bar associated with each plotted attenuation data point indicates the 95-per-cent confidence limits upon the mean. The bar represents the variance due to repeat testing.

The attenuation for 4-sided enclosures is reported as the average determined at 108 positions about the circumference of the tank. Readings were taken every 10 degrees of azimuth for the three distances reported. The attenuation for 2-sided and 3-sided enclosures is given as the average of the attenuations measured at 30 positions in the 90-degree sector shown in the sketches in Figs. 8 and 9.

The data for 4-sided enclosures show that the attenuation was relatively independent of wall height or spacing for the range reported in Table I. The data plotted in Fig. 7 do not correlate with the attenuation predicted from the diffraction theory because the assumptions made do not apply to this configuration. Gettys and Conover[1] have reported similar results. It may be that the 4-sided enclosure should be considered as an open-ended tube from an analytical viewpoint,

The sound follows up the tube to the open end without appreciable attenuation. The attenuation observed at the ground plane is then a function of the dimensions of the open end of the tube and amplitude and phase of the pressure across the opening. Even with an acoustic lining, the attenuation of pressure should be negligible as the sound travels up the enclosure for heights of only 10 feet above the transformer cover. Therefore the effect of wall height an observed sound attenuation would be small at distances far from the transformer and enclosure.

The data for 2- and 3-sided enclosures appear to correlate with the diffraction theory. The agreement of test results and calculated values for the 3-sided enclosures is best for the higher values of *n*. These correspond to wall heights of 10 feet above the transformer cover. At lower heights and *n*'s the tests give higher attenuation than the theory predicts. A definite correlation between the theory and the test data may be observed for the 2-sided model enclosures.

From these data it would appear reasonable to design 2- and 3-sided enclosures on the basis of the diffraction theory of Fehr and Wells and to allow a loss of attenuation due to the build-up within the enclosure. A properly designed acoustic lining would eliminate the the build-up.

Fig. 10 shows a 125,000-kva model transformer with a 3-wall enclosure sound barrier in place. The noise level on the open side of a 2- or 3-sided enclosure is affected by the presence of the barrier, as is shown in Fig. 11. The increase in noise level upon the open side was as much as the build-up in the enclosure. Fig. 11 shows that the presence of the barrier alters the sound field appreciably. The attenuation on the barrier side and the increase of sound on the open side of the enclosure are not constant, but vary over a considerable range. All data reported here are averages, and must be treated as such. If more precise data are required of a particular installation, it is recommended that a scale model of the installation be investigated.

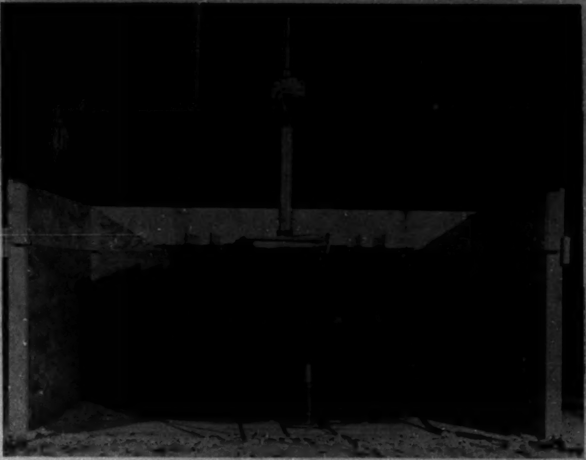

Fig. 10. A 125,000-kva model transformer with a 3-wall enclosure sound barrier in place

TRANSMISSION LOSS THROUGH BARRIER MATERIAL

Noise pressure and vibration measurements were taken about the barrier walls to determine the transmission loss through the wall. From several repeat measurements, the following data were obtained:

Sound Pressure Measurements:

Average pressure inside wall, 87.8 db (flat weighting).

Average pressure one inch from outside wall, 60.8 db (flat weighting).

(Pressure measurements were taken at one-third and two-thirds tank height.)

Wall Vibration Velocity Measurements:

Maximum observed velocity reading, 5.4 centimeters per second rms.

Average observed velocity reading, 2.1 centimeters per second rms.

The noise pressure resulting from a plane wave vibrating at 5.4 centimeters per second rms is 61 db.

It was concluded that wall vibration was not a limiting factor in the tests reported.

Sound Cancellation

Recent tests have demonstrated the practicability of projecting a "beam of silence" through the complex sound field which surrounds a transformer. Although at the present stage of development the beam is limited to a width of about 30 degrees, this is sufficient to eliminate complaints in some installations. The equipment required to do this consists of from one to four loudspeakers, a source of a fraction of a watt of electric power containing the harmonics of noise to be eliminated, and a means of adjusting the phase and amplitude of each harmonic. The cost of this equipment is a small fraction of the cost of conventional sound barriers.

THEORY OF OPERATION

To understand how sound cancellation can be obtained, it must be realized that at large distances a transformer appears to

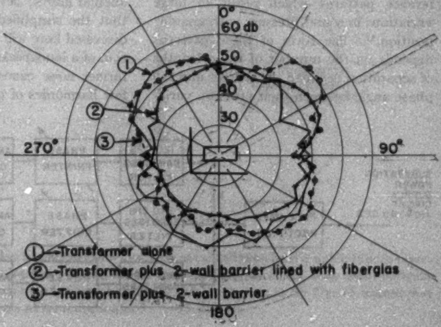

Fig. 11. Polar plot of fundamental frequency noise for 1,500-kva model with and without 2-wall sound barrier in place. Microphone on 81-foot radius to scale from tank center; microphone height 7 feet above ground plane. Measurements taken on flat weighting network

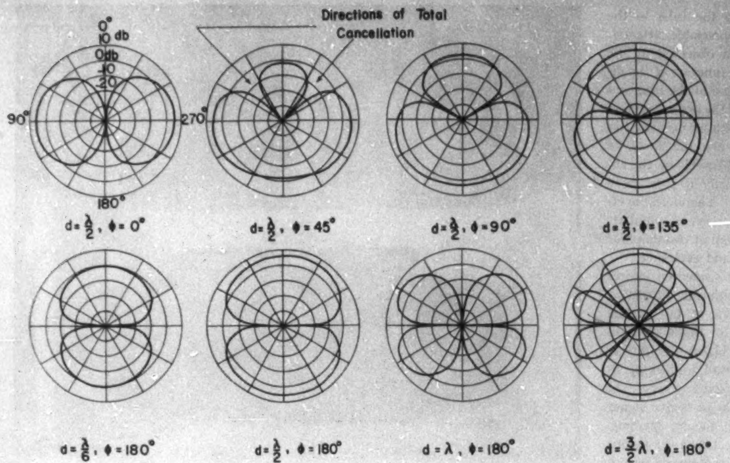

Fig. 12. Directional characteristics of a pair of point sound sources of equal strength. Sources lie on $\theta=0$-degree axis. d = distance between sources, ϕ = phase angle between source sound pressures. Sound pressure given in db with respect to pressure from either source operating alone

be a point source of sound in so far as measurements made along a fixed radial line are concerned; i.e., an observer will find a 6-db reduction in sound level each time his distance from the transformer is doubled. Furthermore, the variation of instantaneous sound pressure with time and radial distance will follow the same law as for a point source. In general, however, the sound pressure will vary with angular position, which is not true of a point source. A formal proof of these statements is given in Appendix II.

At distances several times the longest dimension of the transformer, it can be considered as a point source of sound, provided that consideration is limited to a relatively narrow radial beam. It is well known that the placement of a second point source of sound in the vicinity of the first one will give rise to interference patterns which result in large variations in sound pressure with angular position.[11] The form of these patterns depends on the number of wave lengths of separation between the sources and the phase angle between their pressure variations. Since discussions of this phenomenon in books on acoustics seem to be restricted to cases of in-phase or opposite-phase operation of the sources, a derivation for the case of an arbitrary phase angle is given in Appendix IV.

Fig. 12 shows some typical polar slots of sound pressure around a pair of point sources of equal strength. A study of these curves will indicate the effect of separation and phase angle on the sound pressure field at large distances from the sources. The important thing to notice from equation 45 and the curves of Fig. 12 is that by proper adjustment of the phase angle of a second source (e.g., a loudspeaker) the sound from the first source (e.g., a power transformer) can can be cancelled in a desired direction.

It has been pointed out that a transformer can only be considered a point source when viewed between rather small angular limits; nevertheless, it is believed that the simplified mathematical model discussed here will help to explain the action of a loudspeaker as a means of transformer noise cancellation. For the first few harmonics of transformer noise a 12-inch loudspeaker in a closed baffle is a fairly accurate model of a point source, so no simplifying assumptions are required to explain its behavior.

FIELD TESTS

The first tests of sound cancellation on an actual transformer installation were made on a 15,000-kva unit located at a substation situated on a flat open field, distant enough from sources of disturbing noise to permit quite satisfactory tests (as field tests go!). The equipment used to effect cancellation was assembled on the basis of ready availability; it by no means represents the ultimate in economy or desirability for permanent installation.

To provide a source of harmonic voltage synchronized with the sound output of the transformer, a full-wave selenium rectifier was plugged into a convenience outlet in the substation. Its output was applied to a 3-channel filter which isolated the 120-, 240-, and 360-cycle components of the rectifier output voltage from each other and permitted adjustments in the phase and magnitude of each. These frequencies were then recombined in an addition network and applied to the input of a power amplifier which in turn drove a

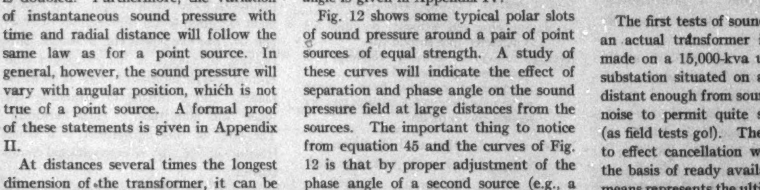

Fig. 13. Block diagram of sound cancellation equipment

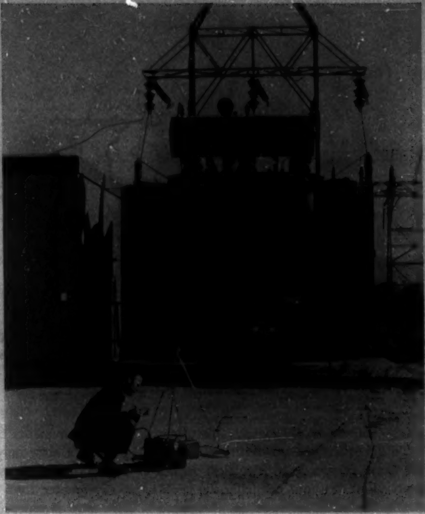

Fig. 14. Measuring sound cancellation on a 15,000-kva transformer in the field. Source of cancellation is a 12-inch loudspeaker in the small box on the side of the tank

loudspeaker. A block diagram of the system is shown in Fig. 13. Successful tests were also conducted in which the output of a vibration meter as used instead of the rectifier. The vibration pickup was fastened to a transformer radiator tube to produce a voltage containing the required harmonics.

The loudspeaker was a 12-inch direct radiator type, mounted in a plywood enclosure. It was held in place near the transformer tank with wire, its location being determined primarily by convenience. Fig. 14 shows a typical loudspeaker placement. In the tests to be described, the loudspeaker faced the tank and was located about 1/2 inch away.

The microphone of the sound level meter was mounted on a tripod at a distance of 100 feet from the transformer on a 0-degree axis arbitrarily drawn through the center of the unit perpendicular to the largest face of its oval tank. The output of the sound level meter was fed to a sound analyzer tuned to 120 cycles. The sound cancellation equipment was energized and the magnitude and phase angle of its excitation were adjusted to give a minimum reading on the sound analyzer. The audible effect of the cancellation was astonishing. Once the adjustment had been made, the transformer noise could be turned off and on at will, merely by switching the loudspeaker on and off.

Without changing the loudspeaker adjustments sound level readings were taken at different angular positions at constant radius with the speaker turned off and on. Fig. 15 shows the results graphically. At locations where the noise reduction was maximal, the balance between transformer noise and speaker noise was rather delicate. The reduction varied between 15 and 35 db momentarily, and appeared to be a function of wind velocity, although other causes are believed to be at least partially responsible. The curves were plotted from estimated average readings.

If the beam width of the silent zone is defined as that angle within which the sound reduction is 6 or more db, it will be noted that the beam width is about 23 degrees. Outside the intended angle of sound reduction, the loudspeaker does not add appreciably to the transformer noise in those regions where it is comparatively high. It does, however, tend to fill in the low-level regions and bring them up to a fairly constant sound level. This is to be expected, since the loudspeaker is very nearly a point source and by itself would therefore put out a con-

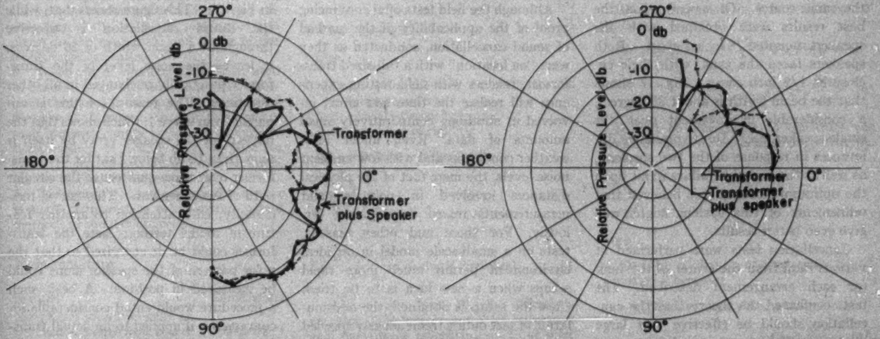

Fig. 15 (left) and Fig. 16 (right). Directional pattern of noise from a 15,000-kva transformer with and without cancellation from a single loudspeaker. Reference level (0 db) is sound pressure without cancellation at 100 feet, 0 degrees. In Fig. 15 the measurements are at 100-foot radial distance from tank and cancellation is adjusted for maximum noise reduction at $\theta = 0$ degrees. The setup for Fig. 16 is the same as for Fig. 15 except that speaker excitation was adjusted to give maximum noise reduction at $\theta = -45$ degrees

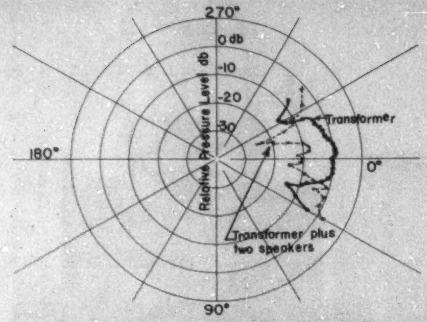

Fig. 17. Directional pattern of noise from a 15,000-kva transformer with and without sound cancellation from two loudspeakers 78 inches apart, operating in parallel. Speaker excitation was adjusted to give maximum noise reduction at $\theta = 0$ degrees

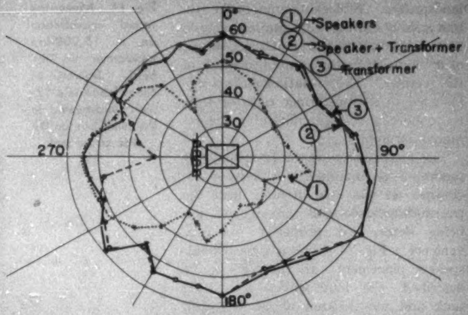

Fig. 18. Sound cancellation test with a 125,000-kva model transformer and a 4 element loudspeaker array. Polar plot is for fundamental frequency of transformer noise

stant sound level in all directions.

To determine the possibility of aiming the beam of silence by electrical adjustment alone, without changing the geometry of the loudspeaker setup, the microphone was placed on the −45-degree radial at a distance of 100 feet. Following the adjustment for minimum noise level at this location, readings were taken in other directions. The results are plotted in Fig. 16. The beam width of the silent zone is only about 13 degrees in this case, probably because of the rather sharp lobe in the sound pattern of the transformer.

To find out if the beam width in the 0-degree direction could be widened without unduly complicating the loudspeaker arrangement, a trial was made with two loudspeakers operating in parallel from the same source. Of several trials, the best results were obtained with the speakers mounted 78 inches apart. Both speakers faced the tank, with their enclosures 1/2 inch away. Fig. 17 shows that the beam width is about 35 degrees, a considerable improvement over the single-speaker test. Due to presumed differences in response of the two speakers, as well as the probable failure to hit upon the optimum location, it is believed that refinements of this system might well give even better results.

Cancellation tests were performed at various radii from the center of the tank for each arrangement described. The tests confirmed the theory that the cancellation should be effective over large distances. Tests out to distances as great as 500 feet indicated that the reduction at any point along a radial line was never less than 6 db.

The data reported here were obtained by measurements on the 120-cycle component of noise only, since in the 15,000-kva transformer used this was substantially greater than the other harmonics. However, it was found in a listening test that when the 360-cycle harmonic was also cancelled the improvement was even more impressive. This was true even though the 360-cycle tone was 15 db below the level of the 120-cycle tone before cancellation was applied.

A comparison of Figs. 15, 16, and 17 shows that the polar pattern of transformer noise is somewhat different in each test. These variations are presumed to result from changes in the vibration pattern of the transformer, in wind velocity, and in air temperature.

LABORATORY TESTS

Although the field tests offer convincing proof of the applicability of the method of sound cancellation, conducted as they were "on location" with a full-sized transformer, readers with field testing experience will realize the time and effort involved in obtaining comparatively small amounts of data. Even under ideal weather conditions and with low ambient noise levels, the mere fact of the physical distances involved in point-by-point measurements retard development seriously. For these and other reasons, tests on a small-scale model in an ideal environment permit much more rapid setups when a new idea is to be tried. Once the setup is obtained, the accumulation of test data is tremendously speeded up.

The availability of a large anechoic chamber makes possible the testing of scale models without problems of ambient noise and weather conditions. The Pittsfield Sound Laboratory has provision for the installation of a plywood floor when tests require the representation of a reflecting ground plane. The simulation, on a model scale, of an ideal site on a flat plain without reflecting structures in the vicinity is thus readily accomplished.

The one-seventh scale model transformer previously referred to was used for the sound cancellation tests conducted in the Laboratory. These tests used a 4-element array of 2-inch loudspeakers to achieve a directional source of sound. Such a source permits cancellation in the desired direction without appreciably affecting the transformer sound pattern in other directions. The behavior of the 4-element array is analyzed in the literature.[12]

The results of a typical test are plotted in Fig. 18. This figure shows that, while the sound cancellation is effective throughout a beam width of 26 degrees, it leaves the noise level of the transformer practically unchanged in all other directions. The reason for this is apparent from curve 1, which shows that the pattern for the speaker array by itself is more than 10 db below that for the transformer over three-quarters of the circular path of measurement. This curve, incidentally, calls attention to another feature of model testing: here the transformer could be de-energized so that the polar pattern of the speaker alone could be measured in position. A best, such a procedure would entail considerable inconvenience if applied to an actual transformer carrying load.

Cancellation tests were made at both the fundamental and the second harmonic of model transformer noise; i.e., at 840 cps and at 1,680 cps. At 1,680 cps, the 4-element array was equivalent to four sources of sound placed in a straight line and spaced one-half wave length apart. Since the same array was used for 840 cps and 1,680 cps, the zone of influence, at 840 cps, covered an appreciably wider angle than it did at 1,680 cps.

Conclusions

SOUND BARRIER TESTS BY MODELS

1. Sound field plots versus radial distance from scale model transformers correlate well with similar test data upon full-scale transformers.
2. Studies of the variation of sound pressure level with azimuth angle about the transformer indicate that the pattern is very complex, and is higher at the ends of the tank than at the sides.
3. Test data indicate that pressure build-up inside a hard-walled barrier subtracts directly from the attenuation possible with a given barrier configuration. For open-walled structures the build-up increases the noise proportionately on the open side.
4. Four-wall barrier data obtained do not correlate with either wall height or spacing from the tank.
5. The attenuation due to 2- and 3-wall barriers may be predicted by simple calculations.

SOUND CANCELLATION

1. By using the technique of sound cancellation, it is possible to reduce transformer noise in a given direction by 6 db or more, over long radial distances, throughout angles up to about 35 degrees.
2. At a given point, noise reductions averaging about 20 db are easily obtainable. (Complete cancellation of a given harmonic is possible for short times, but slight changes in the delicate balance of sound pressures occur momentarily, preventing continuous complete cancellation.)
3. The angular position of the beam of silence may be changed without altering the geometry of the setup, by making adjustments in the magnitude and phase of the loudspeaker excitation.
4. When one or two loudspeakers are used to cancel transformer noise in a given direction, the noise is increased in some other directions. However, in situations where such increases cannot be tolerated, a directional source of sound may be used to effect the desired cancellation without altering the original field elsewhere.
5. The cost of a sound cancellation system is small compared to other sound control methods of equal effectiveness.

φ = longitude in spherical co-ordinate system	
ω = angular frequency	T^{-1}

Appendix I. Requirements for Scaling Structures

As a review of the use of models, it will be well to consider the requirements necessary to permit the scaling of elastic structures. Referring to article 91, page 133 of reference 13, let $\mathbf{w}$ be the vector displacement in the curvilinear co-ordinate system. The vector equation of equilibrium appears as

$$(\lambda+\mu)\nabla(\nabla\cdot\mathbf{w})+\mu\nabla^2\mathbf{w}+\rho\mathbf{F}=\rho\frac{\partial^2\mathbf{w}}{\partial t^2} \quad (1)$$

This equation may be transformed to

$$(\lambda+2\mu)\nabla(\nabla\cdot\mathbf{w})-\mu\nabla\times\nabla\times\mathbf{w}+\rho\mathbf{F}=\rho\frac{\partial^2\mathbf{w}}{\partial t^2} \quad (2)$$

$$\mathbf{w}=\mathbf{i}_1u+\mathbf{i}_2v+\mathbf{i}_3w \quad (3)$$

where

$\mathbf{i}_1$, $\mathbf{i}_2$, and $\mathbf{i}_3$ are the unit vectors in the co-ordinate system
λ and μ are elastic coefficients
μ is the modulus of rigidity

If σ = Poisson's ratio, then

$$\sigma=\frac{\lambda}{2(\lambda+\mu)}$$

and

$$E=\frac{\mu(3\lambda+2\mu)}{\lambda+\mu}\ \text{(Young's modulus)} \quad (4)$$

Observe the form of the differential operator $\nabla(\ )$; $\nabla\cdot(\ )$; and $\nabla\times(\ )$ in orthogonal curvilinear co-ordinates. From reference 14, section 1.16, page 47

$$\nabla\Phi=\sum_{j=1}^{3}\frac{1}{h_j}\frac{\partial\Phi}{\partial X_j}\mathbf{i}_j \quad (5)$$

$$\nabla\cdot\mathbf{w}=\frac{1}{h_1h_2h_3}\left(\frac{\partial}{\partial x_1}(h_2h_3u)+\frac{\partial}{\partial x_2}(h_1h_3v)+\frac{\partial}{\partial x_3}(h_1h_2w)\right) \quad (6)$$

$$\nabla\times\mathbf{w}=\frac{1}{h_1h_2h_3}\begin{vmatrix} h_1\mathbf{i}_1 & h_2\mathbf{i}_2 & h_3\mathbf{i}_3 \\ \frac{\partial}{\partial x_1} & \frac{\partial}{\partial x_2} & \frac{\partial}{\partial x_3} \\ h_1u & h_2v & h_3w \end{vmatrix} \quad (7)$$

h_1, h_2, and h_3 are defined as follows. The elementary cell bounded by co-ordinate surfaces is a rectangular box whose edges are $ds_1=h_1dx_1$, $ds_2=h_2dx_2$, and $ds_3=h_3dx_3$. The box volume is

$$dv=(h_1h_2h_3)\,(dx_1dx_2dx_3)$$

Note that the product h_iX_i has the dimension of length. Notice also that the three operators have the dimension (length)$^{-1}$. Two operations such as $\nabla\times\nabla\times\mathbf{w}$ have the dimension (length)$^{-2}$.

We now change the scale of the geometric system such that a new co-ordinate system $h_i'X_i'=Lh_iX_L$. L will be a dimensionless scale factor. For $L<1$ the new system is physically smaller than the original system. For a 1/7 scale, $L=1/7$.

Let $\mathbf{w}'$ be the displacement in the scaled system. Point for point, we desire $\mathbf{w}'$ to be linearly related to $\mathbf{w}$,$\mathbf{w}'::\alpha\mathbf{w}$. The equation of motion in the new system becomes

$$(\lambda'+2\mu')\nabla'(\nabla'\cdot\mathbf{w}')-\mu'(\nabla'\times\nabla'\times\mathbf{w}')+\rho'\mathbf{F}'=\rho'\frac{\partial^2\mathbf{w}'}{\partial t'^2} \quad (2')$$

The primes indicate the new system. The primed operators are related to their unprimed counterparts by

$$\begin{aligned}\nabla'(\nabla'\cdot[\ ])&=\frac{1}{L^2}\nabla(\nabla.[\ ])\\ \nabla'\times\nabla'\times[\ ]&=\frac{1}{L^2}\nabla\times\nabla\times[\ ]\end{aligned} \quad (8)$$

Substituting relations 8 into equation 2′ yields

$$\frac{1}{L^2}(\lambda'+2\mu')\nabla(\nabla\cdot\mathbf{w}')-\frac{1}{L^2}\mu'\nabla\times\nabla\times\mathbf{w}'+\rho'\mathbf{F}'=\rho'\frac{\partial^2\mathbf{w}'}{\partial t'^2} \quad (9)$$

It will be convenient to construct the model of the same material as the prototype. Hence

$$\lambda=\lambda'$$

$$\mu=\mu'$$

$$\rho=\rho'$$

Also, by a change of time scale $t'=Lt$, equation 9 becomes

$$(\lambda+2\mu)\nabla(\nabla\cdot\mathbf{w}')-\mu\nabla\times\nabla\times\mathbf{w}'+L^2\rho\mathbf{F}'=\rho\frac{\partial^2\mathbf{w}'}{\partial t^2} \quad (10)$$

Equation 10 cannot admit of similarity to equation 2 unless certain restrictions are placed upon the body forces. The restrictions may take the form:

1. **F**′ and **F** nontime-variant (forces such as gravity).
2. **F**′ scaled as $1/L^2$ **F** if time variant.

In the study of models, the only body force usually present is gravity. The gravity body force causes the body to assume some rest displacement. All displacement of oscillatory nature will be measured relative to the rest position of the body. It is customary to subtract the rest position displacements so that for body forces such as gravity equation 10 reduces to

$$(\lambda+2\mu)\nabla(\nabla\cdot\mathbf{w}')-\mu\nabla\times\nabla\times\mathbf{w}'=\rho\frac{\partial^2\mathbf{w}'}{\partial t'^2} \tag{11}$$

and

$$(\lambda+2\mu)\nabla(\nabla\cdot\mathbf{w})-\mu\nabla\times\nabla\times\mathbf{w}=\rho\frac{\partial^2\mathbf{w}}{\partial t^2} \tag{12}$$

The system admits of scaling in this case.

Scaling of Fluid Structures

For fluids there is no shear rigidity. With zero viscosity or for waves with no rotation the equation of motion becomes

$$\frac{K}{\rho}\nabla(\nabla.\mathbf{w})=\frac{\partial^2\mathbf{w}}{\partial t^2} \tag{13}$$

This equation is subject to the restrictions regarding body forces mentioned previously in the section on elastic structures. ρ is the mass density of the fluid; K, the bulk modulus, is defined as $p=-K\nabla.\mathbf{w}$; p is the excess pressure over the rest value. The requirements for scaling fluids, therefore, are the same as for scaling elastic solids.

Upon Scaling Compound Structures such as Braced Liquid-Filled Tanks

Consider a braced tank. Each part of the tank will have its dynamic counterpart in a scaled part of a model tank. Suppose the model deflections are to the full-scale deflections as the scale ratio **w**′ proportional to L**w**.

The resulting stresses in the model will be equal to those in the prototype. This follows since the stresses (or pressures) are dependent upon first space derivatives of displacement; i.e., functions of $\nabla(\ )$ or $\nabla\cdot(\ )$, and upon the elastic constants λ and μ, which are assumed the same for model and prototype. Therefore, the boundary stresses upon the model are exactly equal to the boundary stresses upon the prototype. Integrated over the boundary surface, the energy attributable to the boundary stresses is

$$W=\int_s\frac{\mathbf{w}}{2}\cdot\mathbf{X}dS \tag{14}$$

where **X** is the boundary stress (vector). The energy in the model will be L^3 times the energy in the prototype.

The internal energy due to elastic deflection is given by the volume integral

$$W=\int_v\frac{1}{2}(e_{ij}X_{ij})dv \tag{15}$$

where e_{ij} is the material strain.

e_{ij} model $=e_{ij}$ prototype

X_{ij} model $=X_{ij}$ prototype

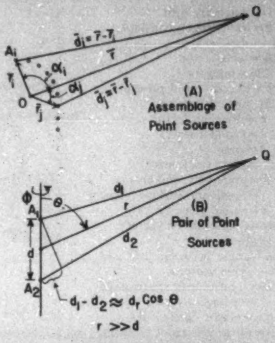

Fig. 19. (A) Arbitrary assemblage of point sources of sound of arbitrary strength, showing nomenclature of generalized position vectors. (B) Pair of point sources aligned on $\theta=0$-degree axis in spherical co-ordinates

hence the internal energy due to elastic deflections in the model would be L^3 times the internal energy of elastic deflection of the prototype.

A similar case exists for the kinetic energy

$$\text{kinetic energy}=\rho/2\int_v\left(\frac{\partial\mathbf{w}}{\partial t}\cdot\frac{\partial\mathbf{w}}{\partial t}\right)dv \tag{16}$$

provided

$\mathbf{w}'=L\mathbf{w}$ for corresponding points

then

$$\frac{\partial\mathbf{w}'}{\partial t'}=\frac{\partial L\mathbf{w}}{\partial Lt}=\frac{\partial\mathbf{w}}{\partial t}$$

Thus the kinetic energy in the model is L^3 times the kinetic energy of the prototype.

Since

$$\frac{\text{Boundary Energy Model}}{\text{Boundary Energy Prototype}}=\frac{\text{Elastic Energy Model}}{\text{Elastic Energy Prototype}}=\frac{\text{Kinetic Energy Model}}{\text{Kinetic Energy Prototype}}$$

and since

$$\frac{\text{Strains and Stresses Model}}{\text{Strains and Stresses Prototype}}=1 \tag{17}$$

provided $\mathbf{w}'\alpha L\mathbf{w}$, then the effects of liquids and individual parts upon one another in the full-size prototypes are matched by equal or scaled effects in the model.

Appendix II. Sound Pressure Field at a Large Distance from a Sound Source of Arbitrary Shape

Consider a surface of arbitrary shape, each point of which is undergoing simple harmonic vibration of the same frequency. The magnitude and phase angle of the vibration of each point are functions of position. The vibrations of the surface will communicate themselves to the surrounding medium and thus radiate sound outward. For the purpose of the analysis which follows, it is convenient to replace this surface by a suitable distribution of point sources of appropriate strength and phase angle.[15]

Examining for the moment a single one of these point sources, it can be shown[16] that the instantaneous sound pressure $p_{\text{inst.}}$ at some point Q, located a distance d from the source, is given by the real part of

$$p_{\text{inst.}}=-j\omega\rho\frac{A'}{d}\epsilon^{j(\omega t+\phi-kd)} \tag{18}$$

Letting $A=-j\omega\rho A'\epsilon^{j\omega t}$, equation 18 may be simplified to read

$$p=\frac{A}{d}\epsilon^{j(\phi-kd)} \tag{19}$$

In equation 19, A represents the complex sound pressure at unit distance from the source; ϕ stands for the phase angle with respect to some chosen reference time axis; and $k=2\pi/\lambda$, where λ is the wave length of sound in the medium under consideration.

Returning now to an assemblage of n such point sources, the total sound pressure p_t at some distant point Q will be, by superposition

$$p_t=\sum_{i=1}^{n}\frac{A_i}{d_i}\epsilon^{j(\phi i-kdi)} \tag{20}$$

In this equation d_i represents the distance between the ith source and the point Q. A_i represents the complex sound pressure due to the ith source at unit distance from it, and ϕ_i is its phase angle.

Referring to Fig. 19(A) which shows the vector distances and their symbols for the ith and jth point sources and the point Q, it is seen that

$$d_i=|\mathbf{r}-\mathbf{r}_i|=\sqrt{(\mathbf{r}-\mathbf{r}_i)\cdot(\mathbf{r}-\mathbf{r}_i)}=\sqrt{\mathbf{r}^2+\mathbf{r}_i^2-2\mathbf{r}\cdot\mathbf{r}_i} \tag{21}$$

$$=\sqrt{r^2+r_i^2-2rr_i\cos\alpha_i}$$

where α_i is the angle between **r** and $\mathbf{r}_i$.

When Q is far removed from the assemblage of point sources (i.e., when $r>>r_i$), r_i is negligible compared to r. Equation 21 may therefore be written

$$d_i\approx\sqrt{r^2-2rr_i\cos\alpha_i}$$

$$=r\sqrt{1-\frac{2r_i}{r}\cos\alpha_i} \tag{22}$$

and since the second term under the radical is very small compared to the first, equation 22 may be further simplified by using the first two terms of the binomial expansion to give

$$d_i\approx r\left(1-\frac{r_i}{r}\cos\alpha_i\right)=r-r_i\cos\alpha_i \tag{23}$$

Because it was specified that $r>>r_i$, equation 23 may be further reduced to $d_i\approx r$. Such an approximation must be used with caution, however. It is valid when applied to the d_i in the denominator of equation 20, but when multiplied by k, as it is in the imaginary exponent of equation 20, it assumes the nature of a phase angle, and because of the periodic nature of angles and their functions the same liberties cannot be taken with it here. Bearing this double standard of approximation in mind, equation 20 may be written

$$p_t \approx \sum_{i=1}^{n} \frac{A_i}{r} e^{j(\phi_i - kr + kr_i \cos \alpha_i)}$$

$$= \frac{e^{-jkr}}{r} \sum_{i=1}^{n} A_i e^{j(\phi_i + kr_i \cos \alpha_i)} \qquad (24)$$

For a given configuration of sources of given strength and phase angle, all the terms under the summation sign in equation 24 are constant except for α_i, which depends on the angular position of point Q with respect to the co-ordinate axes.

Because α_i varies with the angular position of Q, the sound pressure is in general a function of position even when Q is at a fixed distance from the origin. However, if the point Q is restricted to lie in a fixed *direction*, all terms under the summation sign are complex constants and their sum must also be a complex constant. If this constant be expressed as $B \exp j\psi$, equation 24 may be written as

$$p_t \approx \frac{B}{r} e^{j(\psi - kr)} \qquad (25)$$

This is identical in form to equation 19 for a single point source, thus indicating that, at a sufficiently large distance, a complex source of sound appears as a point source to an observer on a radial line of fixed direction.

Appendix III. Spherical Model Approximation to a Transformer Tank

The sphere appears to be another possible simple mathematical model to represent a transformer tank. It is realized that this model is far from an accurate representation because transformer tanks are frequently rectangular in plan and elevation views and because the acoustically hard ground plane requires than an image be located underground. The source is thus more pencil-like than spherical. However, at distances from the tank, the representation of the pressure waves by spherical terms becomes quite accurate.

The expression for the velocity potential for an outward travelling wave becomes in spherical co-ordinates (reference 14, pages 404 and 406)

$$\Phi(r,\theta,\phi) = \sqrt{\frac{\pi}{2kr}} \sum_{n=0}^{\infty} H_{n+1/2}^{(1)}(Kr) \times \left(a_{n0} P_n (\cos\theta) + \sum_{m=1}^{n} (a_{mn} \cos m\phi + b_{mn} \sin m\phi) P_n^m (\cos\theta) \right) e^{-j\omega t} \qquad (26)$$

where $K = \omega/c$ when c = the sonic velocity. The term $P_n^m(\cos\theta)$ is equal to

$$\frac{(\sin^2\theta)^{m/2}}{2^n n!} \frac{\partial^{n+m}(-\sin^2\theta)^n}{\partial(\cos\theta)^{n+m}} \qquad (27)$$

Functions of the simplest θ variation for $m \neq 0$ are obtained by equating m and n

$$P_n^n(\cos\theta) = \frac{(2n)! \sin^n \theta}{2^n n!} \qquad (28)$$

The radiation from a sphere vibrating with the prescribed velocity

$$V_r/r = V_n P_n^n(\cos\theta) \cos n\phi e^{-j\omega t} \qquad (29)$$

is

$$\Phi = \frac{\dfrac{V_n'}{\sqrt{Kr}} H_{n+1/2}^{(1)}(Kr) \cos n\phi \sin^n \theta e^{-j\omega t}}{K\left(\dfrac{n+1}{(KR)^{3/2}} H_{n+1/2}^{(1)}(KR) - \dfrac{1}{\sqrt{KR}} H_{n-1/2}(KR) \right)} \qquad (30)$$

where R is the radius of the sphere.

The acoustic pressure is given by

$$P = \rho \frac{\partial\Phi}{\partial t} \qquad (31)$$

$$= -j\omega\rho\Phi$$

where ρ is the mass density of the fluid.

$$P = \rho c V_n \times \frac{\dfrac{1}{\sqrt{Kr}} H_{n+1/2}^{(1)}(Kr) \cos n\phi \sin^n \theta}{\dfrac{n+1}{(KR)^{3/2}} H_{n+1/2}^{(1)}(KR) - \dfrac{1}{\sqrt{KR}} H_{n-1/2}(KR)} e^{-j\omega t} \qquad (32)$$

The noninteger order Hankel function of the first kind is defined by

$$H_\nu^{(1)}(Kr) = J_\nu(Kr) + jY_\nu(Kr) \qquad (33)$$

From page 64, reference 17

$$Y_\nu(Kr) = \frac{J_\nu(Kr) \cos \nu\pi - J_{-\nu}(Kr)}{\sin \nu\pi} \qquad (34)$$

for $\nu \neq$ integer.

For $\nu = n + 1/2$

$$Y_{n+1/2}(Kr) = (-1)^{n+1} J_{-(n+1/2)}(Kr) \qquad (35)$$

and the Hankel function of equation 33 becomes

$$H_{n+1/2}^{(1)}(Kr) = J_{n+1/2}(Kr) + j(-1)^{n+1} J_{-(n+1/2)}(Kr) \qquad (36)$$

The numerical values of $1/\sqrt{Kr} H_{n+1/2}^{(1)}(Kr)$ have been plotted in Fig. 20 for several values of n. The amplitude has been plotted in units of $20 \log \left| \frac{1}{\sqrt{Kr}} H_{n+1/2}^{(1)}(Kr) \right|$. The pressure radiated from a sphere of radius $R = 3/K$ has been plotted in Fig. 21 for several different vibration modes described in equation 32.

Two points of interest may be observed in the curves. First, notice the near-field effect in the 8- and 12-node modes. Although the pressures at the surface of the sphere for the various modes are within 10 db of each other, the pressure caused by the 4-node pattern is considerably greater than for the 12-node pattern at distances $r > 10/K$. The second point of interest is that, for the

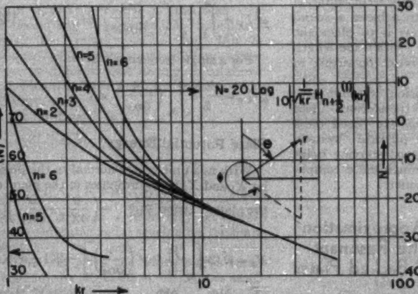

Fig. 20. Graph of magnitude of one-half order Hankel functions versus argument

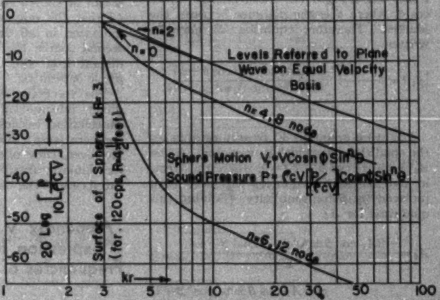

Fig. 21. Sound pressure versus distance from a sphere for several vibration modes

modes plotted, at distances $r>10/K$ the change of pressure level with distance is 6 db per distance doubled.

Appendix IV. Sound Pressure Field at a Large Distance from Two Point Sources

When only two points sources are involved, equation 20 becomes

$$p_t=\frac{A_1}{d_1}e^{j(\phi_1-kd_1)}+\frac{A_2}{d_2}e^{j(\phi_2-kd_2)} \quad (37)$$

A spherical co-ordinate system r, θ, φ will be used in which the $\theta=0$ axis is aligned so that it passes through the point sources. The origin of the co-ordinate system is placed midway between the sources. The geometry of the arrangement is sketched in Fig. 19(B).

Of primary concern is the absolute value of the sound pressure, so equation 37 is first multiplied by its conjugate p_t^*, giving

$$\begin{aligned}|p_t|^2=p_tp_t^*=&\left(\frac{A_1}{d_1}e^{j(\phi_1-kd_1)}+\right.\\&\left.\frac{A_2}{d_2}e^{j(\phi_2-kd_2)}\right)\left(\frac{A_1^*}{d_1}e^{-j(\phi_1-kd_1)}+\right.\\&\left.\frac{A_2^*}{d_2}e^{-j(\phi_2-kd_2)}\right)=\frac{A_1A_1^*}{d_1^2}+\frac{A_2A_2^*}{d_2^2}+\\&\frac{A_1A_2^*}{d_1d_2}e^{j[\phi_1-\phi_2+k(d_2-d_1)]}+\\&\frac{A_1^*A_2}{d_1d_2}e^{-j[\phi_1-\phi_2+k(d_2-d_1)]}\end{aligned} \quad (38)$$

The analysis will be restricted to the sound pressures at large distances from the origin; i.e., $r>>d$. Hence, $d_1\approx d_2\approx r$. The phase angle between the two sources $\phi_1-\phi_2$ can be replaced by ϕ. Then equation 38 becomes

$$\begin{aligned}|p_t|^2=&\frac{|A_1|^2}{r^2}+\frac{|A_2|^2}{r^2}+\\&2R\left(\frac{A_1A_2^*}{r^2}e^{j[\phi+k(d_2-d_1)]}\right)\end{aligned} \quad (39)$$

Since A_1 and A_2 have the same arguments, $A_1A_2^*=|A_1A_2|$. All terms are now real, so the bars indicating absolute magnitudes will be dropped from the A's for convenience. Also, Fig. 19(B) shows that $d_2-d_1\approx d\cos\theta$, where d is the distance between the sources. Therefore equation 39 may be written

$$|p_t|^2=\frac{A_1^2+A_2^2+2A_1A_2\cos(kd\cos\theta+\phi)}{r^2} \quad (40)$$

Equating equation 40 to zero establishes the conditions for which p_t vanishes. Then $A_2^2+2A_1A_2\cos\beta+A_1^2=0$, where the terms in parenthesis in equation 40 have been replaced by β for simplicity. Solving this quadratic for A_2

$$\begin{aligned}A_2&=\frac{-2A_1\cos\beta\pm\sqrt{4A_1^2\cos^2\beta-4A_1^2}}{2}\\&=-A_1(\cos\beta\pm\sqrt{\cos^2\beta-1})\end{aligned}$$

Therefore

$$A_2=-A_1(\cos\beta\pm i\sin\beta) \quad (41)$$

Since A_2 is real, this equation is satisfied only if $\sin\beta=0$. Therefore, $\beta=0$, π. But A_2 must be positive, so $\cos\beta$ must be negative, and β can only equal π. Hence, the conditions for zero sound pressures at large distances are

$$A_2=A_1 \quad (42)$$

$$\beta=kd\cos\theta+\phi=\pi \quad (43)$$

Thus the sound pressure can be made zero at any given distant point by properly adjusting ϕ, provided that $A_2=A_1$.

Replacing A_2 by A_1 in equation 40 in accordance with this finding, and extracting the square root, gives

$$|p_t|=\sqrt{2}\frac{A_1}{r}\sqrt{1+\cos(kd\cos\theta+\phi)}$$

A well-known trigonometric identity enables simplification of this to

$$|p_t|=\frac{2A_1}{r}\cos\left(\frac{kd}{2}\cos\theta+\frac{\phi}{2}\right) \quad (44)$$

To express the sound pressure from two equal sources as a ratio to the pressure from one source operating alone, $|p_t|$ is divided by $|p_1|=\sqrt{p_1p_1^*}=A_1/r$. Also, it is convenient to express distances in terms of wave length, so k will be replaced by $2\pi/\lambda$. The result is

$$\left|\frac{p_t}{p_1}\right|=\pm 2\cos\left(\frac{\pi d}{\lambda}\cos\theta+\frac{\phi}{2}\right);\quad (r\gg d,\ A_1=A_2) \quad (45)$$

Examination of equation 45 shows:

1. The magnitude of pressure about a pair of point sources of equal strength is always symmetrical about the $\theta=0$ axis, since $\cos(-\theta)=\cos\theta$.
2. The sound pressure pattern for a given separation and phase angle is independent of φ, the longitudinal angle is the spherical co-ordinate system as oriented here.
3. The maximum possible value of sound pressure from a pair of point sources is twice that for a single source.
4. A sound pressure of zero can be obtained in any direction by properly adjusting the phase angle between the two sources.
5. The sound pressure will approach zero at all distant locations if the separation of the sources approaches zero and they are oppositely phased; i.e., if $d\ll\lambda$, $\phi=\pi$ radians.

Although it is not obvious by inspection, it can be shown fairly easily from equation 45 that the only way to achieve a sound reduction in all directions is to place the second source less than 1/6th wave length distant from the first source operating in phase opposition.

The foregoing conclusions do not give direct information on transformer noise cancellation because they are based on a comparatively simple physical system. However, they offer a good starting point for thinking about the much more complicated case of the transformer.

Appendix V. Approximation Expression for the Resonant Frequencies of Oil-Backed Plates

This analysis relies entirely on Rayleigh's approach to the calculation of the resonant frequencies. The following assumptions were used to simplify the analysis:

1. Plates are assumed to be infinite in extent.
2. Oil is assumed infinite in extent with no obstructions, but on one side of the plate only.
3. Air loading is negligible.
4. For the sizes of plates and resonant frequencies considered the compressibility of oil will be neglected. In other words, the dimensions of the shortest span between nodes in the vibration pattern will be assumed shorter than 1/4th wave length in the oil.

The analysis proceeds with the use of a displacement potential function defined as

w displacement = −gradient of Φ

$$\mathbf{w}=-\nabla\Phi \quad (46)$$

$$\mathbf{V}=\frac{\partial\mathbf{w}}{\partial t}=-\frac{\partial\nabla\Phi}{\partial t}$$

For Rayleigh's method the energies in the plate and oil are required.

For the Fluid (Oil)

The kinetic energy is given by

$$\omega^2T_0=\rho_0/2\int_v\mathbf{V}\cdot\mathbf{V}/dv \quad (47)$$

Thus

$$\omega^2T_0=\rho_0/2\int_v\left(-\frac{\partial\nabla\Phi}{\partial t}\cdot-\frac{\partial\nabla\Phi}{\partial t}\right)dv \quad (48)$$

For a single-frequency sine wave

$$\omega^2T_0=\frac{\omega^2\rho_0}{2}\int_v\nabla\Phi\cdot\nabla\Phi\,dv \quad (49)$$

The potential energy is

$$V_0=\frac{\rho_0c^2}{2}\int_v(\nabla^2\Phi)^2\,dv \quad (50)$$

For the Tank Wall or Plate

Let $\mathbf{n}_2$ be a unit vector normal to the surface of the wall. Let $\partial/(\partial\mathbf{n}_2)$ denote derivatives in the $\mathbf{n}_2$ direction. Then if S_2 is the plate surface

$$\omega^2T_p=\int_{S_2}\frac{t_2\rho_2}{2}\left(-\frac{\partial^2\Phi}{\partial\mathbf{n}_2\partial t}\right)^2ds_2 \quad (51)$$

For a single-frequency sine wave

$$\omega^2T_p=\frac{\omega^2t_2\rho_2}{2}\int_{S_2}\left(\frac{\partial\Phi}{\partial\mathbf{n}_2}\right)^2ds_2 \quad (52)$$

Plate Potential Energy

With $\mathbf{n}_2$ a unit vector normal to the plate, let X_1 and X_2 be co-ordinates in the plane of the plate. Define $\nabla_{12}^2(\ )=\left(\frac{\partial^2}{\partial X_1^2}+\frac{\partial^2}{\partial X_2^2}\right)(\ )$

$$\begin{aligned}V_p=D/2\int_{S2}&\left\{\left[\nabla_{12}^2\left(\frac{\partial\Phi}{\partial\mathbf{n}_2}\right)\right]^2-2(1-\sigma)\times\right.\\&\left.\left[\frac{\partial^3\Phi}{\partial\mathbf{n}_2\partial X_2^2}\frac{\partial^3\Phi}{\partial\mathbf{n}_2\partial X_1^2}-\left(\frac{\partial^3\Phi}{\partial\mathbf{n}_2\partial X_1\partial X_2}\right)^2\right]\right\}dS_2\end{aligned} \quad (53)$$

$$D=\frac{E_s t_2^3}{12(1-\sigma^2)}$$

Frequency Equation

Assume a mode in the plate

$$w=w_0 \sin\frac{\pi y}{A}\sin\frac{\pi X}{B}\sin \omega t \tag{54}$$

The corresponding oil motion will be matched to the plate motion at the boundary $Z=0$. The simplified equation of motion for a fluid is in terms of the displacement potential function

$$\nabla^2\Phi=\frac{1}{c^2}\frac{\partial^2\Phi}{\partial t^2} \tag{55}$$

If a sine wave time variation is assumed, equation 55 reduces to

$$\nabla^2\Phi+K^2\Phi=0 \tag{56}$$

where

$$K=\omega/c \tag{57}$$

In rectangular co-ordinates, with trigonometric variations in x and y, the solution of equation 56 is

$$\Phi=\Phi_0 \begin{matrix}\sin\\ \cos\end{matrix}\frac{\pi x}{B}\begin{matrix}\sin\\ \cos\end{matrix}\frac{\pi y}{A}\times \epsilon^{\pm\sqrt{(\pi/B)^2+(\pi/A)^2-K^2}\,z}\begin{matrix}\sin\\ \cos\end{matrix}\omega t \tag{58}$$

Now, the radical in the exponent of equation 58 will be investigated. Let $\alpha=\pi/A$, $\beta=\pi/B$. It is possible to show that for small A and B compared to a wave length of vibration in the oil, the radical may be approximated by

$$\sqrt{\alpha^2+\beta^2-K^2}\approx\sqrt{\alpha^2+\beta^2} \tag{59}$$

and the fluid flow is essentially incompressible.

Rewriting equation 59 in more convenient form

$$\sqrt{\alpha^2+\beta^2-K^2}=\sqrt{\alpha^2+\beta^2}\sqrt{1-\frac{K^2}{\alpha^2+\beta^2}}$$

For $K^2/(\alpha^2+\beta^2)$ small, the expression may be further reduced to

$$\sqrt{\alpha^2+\beta^2-K^2}=\sqrt{\alpha^2+\beta^2}\left(1-\frac{1}{2}\frac{K^2}{\alpha^2+\beta^2}\right)$$

An arbitrary limit will be set that if the factor $1/2[K^2/(\alpha^2+\beta^2)]$ is less than 0.05 its effects will be neglected in the calculations; i.e., incompressible flow will be assumed. These equations will hold within 5 per cent for kinetic energy calculations, and within 2.5 per cent for frequency determination.

The limit for K is

$$K^2<0.1(\alpha^2+\beta^2) \tag{60}$$

Thus

$$\omega/c<0.316\sqrt{(\pi/A)^2+(\pi/B)^2} \tag{61}$$

But $\omega|c=2\pi|\lambda$, so a limit may be written on the allowable nodal spacing for the limits listed.

Table III gives the wave length versus frequency for 10-C oil at 50 degrees centigrade, where

$C_{50°}=1.325\times10^5$ centimeters per second
$=5.22\times10^4$ inches per second

Table III. Wave Length Versus Frequency for 10-C Oil at 50 Degrees Centigrade

f, CPS	λ, Inches
120	435
240	217
360	145
480	108.5
600	87
720	72.4
840	62.2
960	54.3
1,080	48.3
1,200	43.5

Most of the vibration work in transformers is concerned with the fundamental component, 120 cps. The limits on A and B at 120 cps will now be determined. Two cases are worth investigating to set a limit on the size A or B may reach and still stay within the assumptions. Equation 61 may be rearranged to make this comparative investigation

$$A<\frac{0.158\lambda}{\sqrt{1+A^2/B^2}} \tag{62}$$

Case A:

$A/B=1$

$A<0.112\lambda$

$A_{120}<49$ inches

Case B:

$A/B\to0$

$A_{120}<68.6$ inches

To summarize, so long as the square node pattern for an oil-backed plate is within 49 inches for 120 cps, the error by assuming incompressible flow will be less than 2.5 per cent. A check for a plate thickness of 1 inch indicates that at 120 cps the condition $A/B=1$ does not approach 49 inches so that the assumption is entirely justified for normal transformer tank plate thicknesses.

Returning to equation 58, the incompressible flow case is given by

$$\Phi=\Phi_0 \begin{matrix}\sin\\ \cos\end{matrix}\frac{\pi x}{B}\begin{matrix}\sin\\ \cos\end{matrix}\frac{\pi y}{A}\times \epsilon^{\pm\sqrt{(\pi/A)^2+(\pi/B)^2}\,z}\begin{matrix}\sin\\ \cos\end{matrix}\omega t \tag{63}$$

The co-ordinate system is chosen with z increasing with further traverse into the fluid. Since Φ cannot go to infinity at an infinite distance from the plate, the plus solution for the exponential is rejected. Similarly matching boundary conditions at the plate requires the sine variations in x and y.

The form of Φ must therefore be

$$\Phi=\Phi_0\sin\frac{\pi x}{B}\sin\frac{\pi y}{A}\times \epsilon^{-z\pi\sqrt{1/A^2+1/B^2}}\sin\omega t \tag{64}$$

$$w=-\frac{\partial\Phi}{\partial z}=\Phi_0\pi\sqrt{1/A^2+1/B^2}\sin\frac{\pi x}{B}\times \sin\frac{\pi y}{A}\epsilon^{-z\pi\sqrt{1/A^2+1/B^2}}\sin\omega t \tag{65}$$

At $z=0$

$$w=\Phi_0\pi\sqrt{1/A^2+1/B^2}\sin\frac{\pi x}{B}\times \sin\frac{\pi y}{A}\sin\omega t \tag{66}$$

Matching boundary conditions, it is found that Φ_0 is related to w_0 of equation 54 by

$$\Phi_0=\frac{w_0}{\pi\sqrt{1/A^2+1/B^2}} \tag{67}$$

which, when substituted into equation 66, gives

$$\Phi=\frac{w_0}{\pi\sqrt{1/A^2+1/B^2}}\sin\frac{\pi x}{B}\sin\frac{\pi y}{A}\times \epsilon^{-\pi z\sqrt{1/A^2+1/B^2}}\sin\omega t \tag{68}$$

To determine the kinetic energy in the fluid, Φ is substituted from equation 68 into equation 49 and the necessary algebra is performed. The result of the integration gives

$$\omega^2T_0=\frac{\omega^2\rho_0}{2}\left(\frac{AB}{4}\right)\left(\frac{1}{\pi\sqrt{1/A^2+1/B^2}}\right)w_0^2 \tag{69}$$

Substitution of w from equation 54 into the expressions 52 and 53 give the following expressions for the plate energies

$$\omega^2T_p=\frac{\omega^2\rho_s t_2}{2}\left(\frac{AB}{4}\right)w_0^2 \tag{70}$$

and

$$V_p=D/2\left(\frac{AB}{4}\right)[(\pi/A)^2+(\pi/B)^2]^2w_0^2 \tag{71}$$

The total kinetic energy in the vibrating system is the sum of equations 69 and 70

$$\omega^2T=\frac{\omega^2\rho_s t_2}{2}\left(\frac{AB}{4}\right)\left(1+\frac{\rho_0}{\pi\rho_s t\sqrt{1/A^2+1/B^2}}\right)w_0^2 \tag{72}$$

The resonant frequency of the nodal spacing $A\times B$ is determined from equations 71 and 72 to be

$$\omega^2=V_p/T \tag{73}$$

$$\omega^2=\frac{\pi^4D}{\rho_s t_2}\frac{(1/B^2+1/A^2)^2}{1+\dfrac{\rho_0}{\pi\rho_s t_2\sqrt{1/A^2+1/B^2}}} \tag{74}$$

Solving for f, one obtains

$$f=\frac{\pi}{2}\sqrt{\frac{E}{12(1-\sigma^2)\rho_s}}\,t_2\times \frac{1/A^2+1/B^2}{\sqrt{1+\dfrac{\rho_0}{\pi\rho_s t_2\sqrt{1/A^2+1/B^2}}}} \tag{75}$$

For steel

$E=30,000,000$ pounds per inch^2

$\sigma=0.3$

$\rho_s=7.35\times10^{-4}\dfrac{\text{pounds per second}^2}{\text{inches}^4}$

For 10-C oil at 20 degrees centigrade

$\rho_o/\rho_s=0.1126$

Change with temperature is relatively unimportant; e.g., at 60 degrees centigrade

$\rho_o/\rho_s=0.1095$

With steel and 10-C oil data, equation 75 reduces to

$$f=9.74\times10^4 t\frac{1/A^2+1/B^2}{\sqrt{1+\dfrac{0.0359}{t\sqrt{1/A^2+1/B^2}}}} \qquad (76)$$

where t, A, B, are in inches.

◆

Discussion

T. R. Specht (Westinghouse Electric Corporation, Sharon, Pa.): These tests with models and the sound cancellation method are very interesting. The comparison of the attenuations secured by 2-, 3-, and 4-sided barriers is quite useful. As I understand the paper, the barrier tests were made at only the fundamental of the sound frequency which is twice the frequency of the applied voltage. It would be interesting to know the attenuation at higher frequencies as well.

In the case of the 2-wall enclosure, the theoretical equation is satisfactory, so it is possible to calculate the attenuation at the higher frequencies. In general, the sound from a transformer contains higher harmonics. The attenuation, due to the wall, of the sound will be larger than as given in the paper because the wall attenuates the higher frequency components more than the fundamental. From Fig. 9 referring to a 2-wall enclosure, the attenuation increases about 3 db each time the frequency doubles. For a 4-wall enclosure, by comparing it to a vibrating piston set in an infinite surface, for constant sound energy radiated, the sound level at some distance from the transformer would decrease again 3 db each time the frequency doubles.

The harmonic content of the sound from transformers varies with various transformers. The harmonic index (HI) is an indication of the amount of harmonic content. Mutschler and Madden[1] give the HI of a transformer as 11.9. C. S. Murray[2] gives an HI for a 60,000-kva transformer of 5.5. I calculated some examples, assuming a sound consisting of various components, with 120 cycles and higher harmonics. The 3-db rule for the increased attenuation for the harmonics was used. The attenuation of the db_{40} sound level between the transformer and some point away from the transformer was calculated. It was observed that this attenuation is about the same for the same HI, for frequencies of the harmonics through 720 cycles. For an HI of 15, the attenuation for the db_{40} sound is 1.5 db greater than for the 120-cycle component; for HI = 12, 3 db more; for HI = 9, 4.4 db more; and HI = 6, 5.2 db more.

Sound cancellation has intriguing possibilities but it would appear that there would be difficulties in applying it in practice. If the transformer and loudspeaker are supplied from the same voltage source, the sound level of the loudspeaker would change 1 db for a 10-per-cent change in voltage and the transformer would change about 3 db. The load current produces a small amount of noise in the transformer. Changes in pressure in the tank would change the modes of vibration of tank panels. Also the loudspeaker and its power source would need to be stable with time. It would be possible for an adverse combination of these factors to make the cancellation ineffective. If there were a bank of transformers, a loudspeaker would have to be placed on each transformer, unless the transformers were grouped closely together and could be considered as a single transformer. A report on a practical installation will certainly be of real interest to all.

2. *Discussion* by **C. S. Murray** of reference 1, p. 118.

William B. Conover and **Robert J. Ringlee:** Mr. Specht is correct; the model barrier data reported were for the fundamental frequency of transformer noise. For the one-seventh scale model this was 840 cps. Two check tests were made with the 2-sided enclosure at the third harmonic of transformer noise, 2,520 cps for the model. These two checks were found to agree closely with the attenuations predicted from the diffraction theory of Wells and Fehr (references 9 and 10 of the paper) using the calculation methods given in our paper. Additional tests are planned with the 3- and 4-sided enclosures at the second, third, and higher harmonic frequencies of transformer noise.

Those accustomed to using the HI as an indication of frequency composition will find Mr. Specht's analysis useful for estimating the effects of partial enclosures upon transformer noise measured upon the *A* network of the sound level meter.

Successful sound cancellation tests have been performed upon three outdoor substations. These tests have shown that the transformer noise varies slowly with time along particular radial directions. A self-compensating system is being developed to follow the variations of transformer noise.

Functional Temperature Endurance Tests on a Silicone Glass Fiber Insulation System for Dry-Type Transformers

M. L. MANNING
FELLOW AIEE

THIS paper is an outgrowth of test procedures agreed upon by the AIEE Working Group on Life of Materials, Subgroup on Functional Tests, under the auspices of the Committee on Transformers of the Power Division. Work on a 15-kv class silicone glass fiber transformer insulation system was assigned to the author. Other members of the Subgroup studied lower temperature insulation systems. Based on the activity of the Subgroup on Functional Tests, additional experimental test work on insulation systems under accelerated conditions to be correlated with actual transformer operating experience has been recommended.[1]

By substantiating data, accelerated functional tests on a silicone glass fiber insulation system are linked with dry-type transformers in service. Support is offered for the recent action by the Transformer Section of the National Electrical Manufacturers Association (NEMA) in establishing 180-degree-centigrade (C) hottest-spot temperature rise for what is classified as group 3 dry-type transformers.[2] Model transformers, 16 in number, having a composite silicone glass fiber insulation system corresponding to 15-kv-class insulation were subjected to heat, 90 per cent (%) humidity and 100% dielectric-proof voltage test-cycling at 200, 275, and 350 C obtained by circulation of current in the windings. Ordinarily in service, dry-type transformers are given only 75% test voltage, in accordance with AIEE Standard No. 53.[3]

Present-Day Practice of Evaluating Insulating Materials for Dry-Type Transformers

A review of present-day practice may be helpful. Basically four procedures are involved. First, AIEE Standard No. 1, which was revised in February 1954,[4] follows the same general material classification since its inception in 1913. Based mainly upon chemical composition, insulating materials are given classifications of *O*, *A*, *B* and *H*. Temperatures of 90, 105, 130, and 180 C respectively are suggested. They are the limiting hottest-spot temperatures at which these classes may be operated continuously with normal life expectancy. Tests are not prescribed to support the classifications. For example, a class *B* designated transformer may use class *A* structural materials as components, yet, according to AIEE No. 1, class *A* is given a 105-C hottest-spot temperature limit. But the transformer is called class *B* which signifies 150-C permissible hottest-spot temperature. The qualifying statements in this standard allow such latitude to exist.

Second, the American Society for Testing Materials standards outline methods for testing various kinds of insulating materials. Suppliers of materials follow these standards and users may duplicate the tests or devise others to be assured that desired properties of materials are obtained. The mechanical and electrical properties are set at the transformer manufacturer's discretion and are not prescribed by the standards.

Third, the American Standards Association Standards for transformers and those of the AIEE specify a limiting temperature rise for a given class of insulation. The temperature values set are in accord with those of AIEE No. 1.

NEMA has divided dry-type transformers into three groups. Group 1 allows a permissible hottest spot temperature rise, 65 C; group 2, 110 C, and group 3, 180 C.[2] This is the initial step taken by standardizing bodies to formulate a workable plan. The user of transformers is confident that in the transformer manufacturer's product these temperature limits are conservative and that considerable margins exist.

The fourth step, or plan, in use for evaluation of insulating materials is made by the transformer manufacturer. The manufacturer screens the materials, observes the characteristics of each material mechanically and electrically, allows margins above test requirements and processes these materials into a transformer insulation system. Considerable conservatism in insulation system designs exists because failures are always costly to a manufacturer, and he must protect his reputation. Users are thus protected by such a general plan of insulating material selection, which has been in use for a number of years by reliable manufacturers.

What Is Needed in New Methods

Present-day practice, as outlined, has several disadvantages. In recent years many new bonding and impregnating resins have been developed for use with base materials such as glass fiber and asbestos. The task becomes quite hopeless in establishing temperature limits on an organic or inorganic basis for numerous materials by assigning to them alphabetical letters. Furthermore, the situation becomes more complicated because of recent action by the International Electrotechnical Commission in suggesting two new insulation classes *E* and *F*.[5]

Standardizing groups dealing with transformer and manufacturing problems require freedom in choosing suitable requirements for insulation and temperature limits. The present arrangement of the AIEE in setting up the Subcommittee on Dielectrics of the Basic Sciences Committee for evaluation of materials alone, plus the Working Group on Life of Materials Committee having a subgroup under the Transformer Committee, is a step in this direction. Wasteful use of time results in having an over-all committee make basic decisions. Freedom of movement is required by dividing the responsibility with smaller committees.

A convenient procedure is necessary for screening new materials, followed by evaluation of these materials in transformer insulation systems. This paper deals with the latter plan, whereby functional testing of an insulation system is utilized after the primary selection of materials has been made. Functional tests of an insulating material system give the practical, accelerated means by which the component parts of the system are evaluated at temperatures, voltage stresses, and humidity conditions found under extreme service conditions. Tem-

perature gradients on component materials differ in a transformer insulation structure. The only true means for determining the behavior of these materials is in a system evaluated functionally by test.

The primary screening of materials may still be classified under letters, *A*, *B*, *H*, etc., with corresponding temperature limits. This may be done without reverting to an organic or inorganic basis by test codes based on life test performance of materials. The second step is the development of test codes for the evaluation of insulation systems by functional test for transformers.

Purpose of Functional Tests for a 15-Kv Insulation System

1. To verify that a 15-kv test model is practical.

2. To devise a practical test procedure utilizing heat, voltage, and humidity cycling.

3. To obtain helpful information for devising a test code for functional temperature endurance tests of dry-type power transformers.

Test Apparatus

TEST MODELS

A test model with component parts, built at an approximate cost of $90 for labor and materials, is illustrated in Figs. 1 and 2. This model represents a typical structure for a 15-kv-class insulated high-voltage winding, with a 1.2-kv-class low-voltage winding and supporting structure. All insulation is glass fiber silicone resin bonded. The high-voltage coil is wound of two parallel conductors to permit a

dielectric test of turn-to-turn insulation. The leads from each pair of twin sections are brought out separately to permit a section-to-section voltage test. The low-voltage winding consists of two layers to permit testing. Thermocouples, nos. 8 and 10, located in the third section of the high-voltage winding, are used to monitor the current flow (Fig. 3) to obtain hottest-spot temperature desired. Models having thermocouples, of course, were not subjected to voltage tests. Ordinarily, greater creepage of about 1-inch high-voltage winding to ground is allowed. The reason for use of the 3-inch distance in the model was to determine if creepage flashover or puncture would occur. Special turn-to-turn insulation was used on five of the test models.

TEST EQUIPMENT FOR HUMIDITY EXPOSURE AND CURRENT CONTROL

For this test a steel tank of bolted construction, 50 inches long, 25 inches wide, and 24 inches high was utilized. To obtain 90% humidity at room temperature, a pan 12 inches wide, 24 inches long, and 2 inches deep containing saturated lead nitrate salt solution was placed in the bottom of the tank. By means of a fan, recirculated air was blown over the solution and through the ducts of the transformer models. For humidity exposure, the aluminum foil wrapping was removed from the models. In Fig. 4, the tank for humidity exposure, the current regulator, and associated control equipment for monitoring current flow in the model transformer windings can be noted. Winding currents of 67, 110, and 150 amperes respectively, were required to obtain hottest-spot temperatures of 200, 275, and 350 C.

TEST PROCEDURE

To maintain the high-voltage and low-voltage barrier insulation temperature

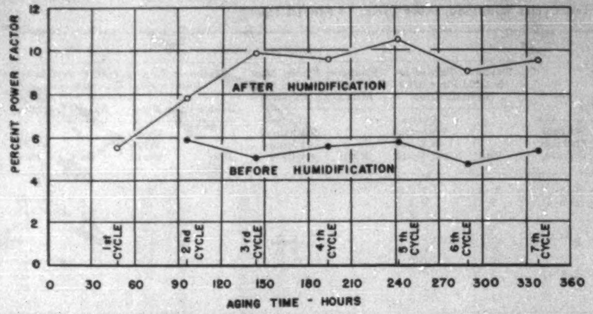

Fig. 5. Pf versus aging time before and after humidification, 90% RH at 32 C, high to low voltage and ground, 15-kv-class dry-type silicone glass fiber transformer system. This also applies in Figs. 6 through 10. Aging temperature 200 C

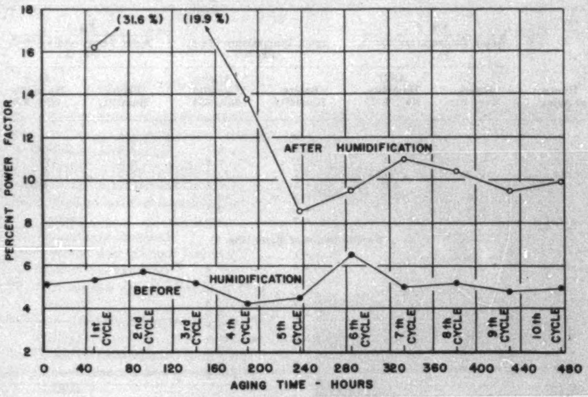

Fig. 6. Aging temperature 275 C

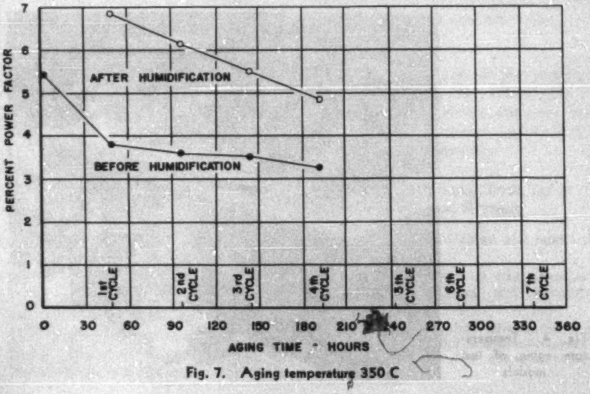

Fig. 7. Aging temperature 350 C

within 25 C of the hottest-spot winding temperatures selected, the air ducts in the structure of the models were blocked by asbestos packing. The entire model was then wrapped with aluminum foil. As many as three models were connected in series with the model having thermocouples for a particular temperature aging. A functional test cycle which follows an initial dielectric proof voltage test on all models except those having thermocouples is outlined in the following. (Of a total of 16 models three were wound with thermocouples.) Two models without aging cycles were subjected to $1^{1}/_{2}$x40 microseconds positive-polarity impulse voltage tests to determine the impulse voltage ratio.

In the functional test cycle, a cycle consists of the following:

1. Heat aging; 48 hours at a given temperature; circulation current in windings.
2. Cooling to ambient temperature 4 hours.
3. Dielectric proof tests.
4. Humidify at 90% relative humidity (RH) for 24 hours.
5. Dielectric proof tests within 1/2 hour after removal from humidity chamber.

The dielectric proof test consists of:

1. American Standards Association standard 100% test voltage for 15-kv-class insulation. Major insulation, high-voltage winding to ground and to low-voltage winding, 1 minute withstand, 31 kv. Section-to-section, 1 minute, 60 cycles, rms 7 kv. Turn-to-turn, 1 minute, 60 cycles, rms 800 volts. Layer-to-layer, low-voltage winding, 1 minute, 60 cycles, rms 5 kv.
2. Power factor (pf) test at room temperature H-LG, L-HG, HL-G.

Comments on Test Results

The heat, humidity, and dielectric proof tests were made in air in accordance with the test procedure outlined in the foregoing. Table I outlines test cycles withstood. (Ordinarily 1-inch greater creepage distance is allowed in actual 15-kv transformer barrier construction. The purpose of clearance used in the models was to determine if puncture or voltage creepage would occur under such cycling.)

Test 1 was discontinued; there was no flashover or evidence of deterioration at 200 C.

For test 2 the following conditions obtained at 275 C:

1. One model; 0.5 cycle withstood. Voltage creepage over barrier-to-ground plate after 90% humidity exposure. Special turn-to-turn insulation used; no failure through 7 cycles.
2. One model; 2.5 cycles withstood.

Voltage creepage over barrier-to-ground plate after humidity exposure. Special turn-to-turn insulation used on this model; no failure through 7 cycles.

3. One model; 6.5 cycles withstood. Voltage creepage over barrier-to-ground plate after humidity exposure. Special turn-to-turn insulation used; no failure through 7 cycles.

4. One model; 7 cycles withstood. Thermocouple unit; no voltage tests.

5. Three models; 1.5 cycles withstood. Voltage creepage over barrier-to-ground plate after humidity exposure. After voltage creepage flashover on barrier insulation, ground plates were removed. Barrier insulation did not puncture at any time even though creepage flashovers to ground occurred from 3.5 up to 8.5 cycles. Turn-to-turn insulation consisting of two wraps of glass fiber failed at 1.5 cycles after humidity exposure.

6. One model with thermocouples; 17 cycles withstood. This model withstood all heat cycling and humidification. Thermocouples were removed at the completion of 17 cycles to make voltage tests. Proof voltage tests were withstood. Flashover occurred on the barrier at 46 kv with the ground plate removed.

For test 3 the following conditions obtained at 350 C:

1. One model; 0.5 cycle withstood. Voltage creepage over barrier-to-ground plate after 90% humidity exposure. Turn-to-turn failure 1.5 cycles. (Two wraps of glass fiber used.)

2. One model; 1.5 cycles withstood. Voltage creepage over barrier-to-ground plate after 90% humidity exposure. Turn-to-turn special insulation withstood 4 cycles, the maximum cycling.

3. One model; 3.5 cycles withstood. Voltage creepage over barrier-to-ground plate after 90% humidity exposure. Turn-to-turn special insulation withstood 4 cycles.

4. One model; four cycles withstood. Thermocouple unit; no voltage tests.

In connection with the power factor before and after humidification, the average 60-cycle voltage values measured at 32 C. Table II and Figs. 5, 6, and 7 list the high-voltage to low-voltage and ground measurements. Table III and Figs. 8, 9, and 10 list the high-voltage and low-voltage to ground measurements.

For location of thermocouples, refer to Fig. 3. Thermocouple readings are found in Table IV for 200-C aging, 7th cycle; in Table V for 275-C aging, 7th cycle; and in Table VI for 350-C aging, 4th cycle.

In the impulse voltage tests two models without heat aging and with ground plates, $1^1/_2$x40 microseconds positive-polarity impulse voltage was applied to the high-voltage winding with the low-voltage winding grounded; see Table VII.

Discussion of Test Results

Cyclic Application of Heat Aging, Cooling, Proof Voltage, Humidification and Proof Voltage

The temperature of the barrier insulation was held within 25 C of aging or hot-test-spot winding temperature. It is important that only 100% proof voltage after humidification caused creepage flashover on barrier insulation after 275- or 350-C heat aging. Flashovers did not occur after humidification at 200-C aging temperature. Neither did flashovers occur after the heat-aging portion of the cycle for the whole range of aging temperatures used. Tests on Motorettes revealed also that humidification is a factor.[6]

Models having thermocouples would withstand aging temperature and humidification indefinitely since they were not subjected to proof voltage. At 275-C heat cycling, the model having thermocouples withstood 17 cycles (34 days' heat aging, 17 days' humidification). At the completion of 17 cycles, this model withstood 100% proof voltage with thermocouples removed up to 45-kv rms maximum withstand 60-cycle voltage after drying at room temperature

Puncture of barrier insulation did not occur during any heat aging temperatures of 200-, 275-, and 350-C aging temperatures. Flashovers occurred only after humidification. Usually in design practice, about a 1-inch greater creepage distance is allowed from the high-voltage winding to ground. Use of the 3-inch creepage distance in the model was to determine if creepage flashover or puncture would occur.

General appearance and condition of the barrier insulation was good after the 200- and the 275-C aging. At 350-C aging, the silicone resin became somewhat deteriorated, but it was in reasonably good condition mechanically. This was noted when models were dismantled. No punctures were found after careful inspection. Of importance also is the fact that these models were aged in air. In nitrogen atmosphere, aging data for silicone insulation shows that for equal thermal aging, the temperature may be increased about 50 C over that of silicones operated in air (ventilated).[7]

Turn-to-Turn Insulation

Glass fiber insulation may be scuffed during the winding operation or the bond of the silicone resin to the glass may be insufficient to withstand extreme heat aging, humidification, and 100% voltage cycling. This may be the reason for the turn-to-turn strength variation found at 275- and 350-C. If the turn-to-turn failure occurs at adjacent points between sections of coils, section-to-section flashover results. If must be remembered that in service, the turn-to-turn voltage stress is much lower than the 800-volt withstand required for this proof test after 90% humidification.

At 275-C aging temperature, the turn-to-turn glass fiber insulation in three models withstood 1.5 cycles. A special wire insulation developed for 15-kv class transformers used in three models withstood the maximum test cycling of 7 cycles.

At 350-C temperature aging, failure occurred in one model using glass fiber insulation at 1.5 cycles. Failures were not found in the two models having special wire insulation.

For the low-voltage layer insulation, during all cycling, the layer insulation withstood 5 kv, 1-minute voltage proof test.

For temperatures in insulation structure as determined by thermocouples, refer to Fig. 3, which gives the location of thermocouples. Tables IV, V, and VI give values at a particular cycle.

Winding current was controlled mainly by thermocouples wound in the third

section of the high-voltage winding on the second and on the sixth turn from the inside of the pancake winding (thermocouples 8 and 9). Note that the temperature was held within ±2 C for the 200- and 275-C settings and within ±1.5% of the 350 C setting.

Temperature maintained on the barrier insulation was within 25C lower temperature than the hottest-spot winding or aging temperatures. This was accomplished by blocking the air ducts with asbestos packing and by carefully wrapping the entire models with aluminum foil.

PF Test Values

In connection with pf test value, see the section "Test Procedure," and Table II. Pf in per cent versus aging time in hours is plotted with the use of before and after humidification conditions in Figs. 5, 6, 7, 8, and 9. After humidification, pf measurements were made within 20 minutes of removal of models from the humidification tank. Before humidification, pf measurements were made at the end of the 4-hour cooling period after the 48-hour temperature aging.

Consider, for example, the high-voltage to low-voltage and ground set of pf measurements. After humidification, pf values fluctuate as normally occurs during moisture release or curing of resin varnish. Before humidification, pf values are practically constant for the entire cycling considered. The initial pf value at 275 C aging is 5.1%. Through 10 cycles of heat aging, the per-cent pf value terminates at 5.1%. In this set of measurements the barrier insulation is predominant in the system.

Constant pf values can be noted also for the before-humidification conditions through all cycling for the high- and low-voltage winding to ground measurements.

These practically unchanged pf values are of significance. Silicone resins because of their water-repellant nature prevent penetration of moisture in small cracks of varnish film. Older kinds of bonding and impregnating resins, after exposure to 90% humidity and heat cycling, may permit entrance of moisture below the surface film. As a result of shrinkage at high temperatures, some resins may become loose and brittle. Silicones have the toughness and resiliency to withstand stresses under abnormal conditions.

Relation of Functional Test Models to Dry-Type Transformers in Service

Transformers, having a similar silicone glass fiber insulation system based on a permissible 180-C hottest-spot rise, have been in use since 1951.[8] Ratings extend from 250- through 2,000-kva, and 5- through 15-kv ratings. Typical core and coil construction for a 500-kva, 3-phase, silicone-insulated transformer appears in Fig. 11. This transformer, with a sealed-in nitrogen enclosure, is illustrated in Fig. 12.

These transformers, utilized for unit substation, network, and station auxiliary service, are designed for 150-C average rise by resistance and 30-C permissible hottest-spot rise. This means that in 40-C maximum ambient temperature, the permissible hottest-spot winding temperature is 220 C in conformity with present NEMA standards for group 3 dry-type transformers. Subjected to varied load and overload conditions, these transformers, now numbering about 100 units, have given excellent performance. Mostly, sealed-in nitrogen construction is utilized to ensure freedom from dirt and contaminating conditions.

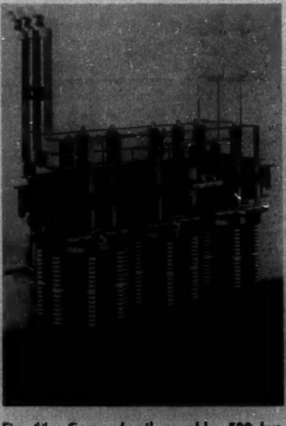

Fig. 11. Core-and-coil assembly, 500 kva, 3-phase, 150-C rise

Model transformers, as described in this paper, were aged at 275- and 350-C temperatures or at least 55- and 130-C higher temperatures than the hottest-spot temperature of 220 C permissible in dry-type transformers. Transformers would seldom be subjected in service to such extreme heat cycling, humidity, and voltage conditions as withstood by models. By functional tests, the user is assured that operating margins exist, that failures become remote, and that the manufacturer has taken care to produce a reliable transformer.

In service, transformers of ventilated construction after being exposed to humid conditions are not frequently subjected to voltages of 31 kv from high-voltage winding to ground. A dry-out period may

Fig. 12. Sealed-in nitrogen transformer, 500-kva, 3-phase, 150-C rise

be allowed or lightning arresters can be utilized. Barrier insulation flashovers, as experienced in the models having less creepage distance (high-voltage winding to ground) than that for 15-kv transformers, become of less concern when operating conditions are considered. In practice, the increased creepage distance utilized lessens the possibility of flashover. The fact remains that cycling and voltage tests did not produce holes in the silicone glass fiber barrier insulation system.

Conclusions

1. Tests demonstrate that a 15-kv class model is practical.

2. By utilizing heat, voltage, and humidity cycling, a functional test procedure on models develops voltage stresses and temperature gradients more severe than those ordinarily found for transformers in service. Tests on a model can be more numerous, varied, and accomplished at less cost than tests on complete transformers. Test data obtained by interested transformer manufacturers can be compared.

3. Silicone insulation system data are now available for a test code on functional temperature endurance tests on ventilated dry-type power and distribution transformers.

4. Failure by puncture of the silicone glass fiber barrier insulation was not obtainable in spite of the severity of the tests. At 200-C aging, no flashovers occurred from the high-voltage winding along the barrier insulation surface to the end of the plate (ground) after humidification in 7 cycles' duration of the test. A 275-C aging, flashovers occurred at 1.5 cycles, but upon removal of the end plates, up to 8.5 cycles were withstood before flashover after humidification in 10 cycles' duration of the test. At 350-C aging, flashovers occurred from 0.5 to a maximum withstand of 3.5 cycles, and end plates were not removed in 4 cycles' duration of test. If flashover occurred after humidification for a given cycle, flashover would again take place after the heat aging and humidification on subsequent cycles.

5. Future consideration should be given to increasing the high-voltage winding to ground clearance in the model used. Ordinarily, a full-sized transformer utilizes about a 1-inch greater creepage distance. But the purpose of the test was realized in determining whether creepage or puncture of the barrier would result for the clearance used. The purpose of the test cycling was to determine its adequacy rather than to test a specific transformer design.

Variable insulation flashovers, without puncture of barriers, constitute a debatable question about failure. Increased creepage distances may change the conditions entirely. Therefore, no attempt was made to plot time of variable flashovers (life) on logarithmic ordinate scale graph paper, having the reciprocal of absolute temperature scale to represent temperature aging as the abscissa.

6. After humidification only, voltage proof testing resulted in barrier flashover. Models having thermocouples withstood all heat cycling through as many as 17 cycles at 275 C (34 days of heat aging, 17 days of humidification at 90% humidity). Models having thermocouples could not be subjected to voltage tests. After thermocouples were removed on the unit exposed to 17 cycles at 275 C, a maximum voltage of 45-kv rms (45% above test) was withstood for 1 minute (high-voltage winding to ground).

7. Even though the turn-to-turn voltage strength and other requirements demanded by the tests exceeds those found for transformers in service, the fact remains that the test method dictates the margin of strength available. Development of insulating materials for wire covering can proceed accordingly.

8. Data presented in this paper for models plus the service record of 100 transformers having similar insulation systems, offer support for the recent action by NEMA in establishing for group 3 transformers a permissible 180-C hottest-spot rise. Ratings of these transformers extend from 250 kva through 2,000 kva, 5- through the 15-kv class, and designs are based on the temperatures proposed by the new NEMA standards.

◆

Discussion

Yale Goldberg (Iowa Power and Light Company, Des Moines, Iowa): When a utility man enters a discussion relative to transformers whether it be concerning design, maintenance or operation, economics are of prime importance. We are familiar with the oil-immersed transformer and the various types of insulation class *A*, class *B*, class *O*, and the comparatively new class *H*.

As the load current in any transformer is increased its temperature rises because of greater losses. The material most subject to damage by heat in a transformer is the insulation. There is insulation in the core and in the windings, but since the core losses are nearly constant for all loads, it is the insulation on the windings which causes concern. It is known that any insulating material deteriorates; that deterioration is a function of both temperature and time; that the higher the temperature the greater the rate of deterioration; and that any operation of a transformer reduces its life.

Through research, an insulation was developed such as class *H* with a suggested limiting hottest-spot temperature of 180 C. A factor such as greater safety in operation because of the use of materials less combustible, as those found in class-*A* insulation in an oil-filled transformer, is important. Oil-filled transformers are probably the most widely used type. Liquid-filled are perhaps next in number used and lastly the dry-type transformer. Safety is a watchword in every utility today. Any improvement in equipment which lends itself to safer operation is given every consideration.

Network areas are usually in dense load sections of town. In these areas large numbers of people move about. Many underground vaults are constructed in sidewalks and open gratings are used for ventilating purposes. When oil-filled transformers are used in installations such as these, there is a hazard to pedestrians passing over the vaults should an explosion occur which could throw hot oil and possibly fire. If a liquid-filled transformer in such a vault should fail or explode, there would be fumes of a pungent nature which could harm pedestrians.

We experienced the failure of a liquid-filled transformer which occurred in a transformer room beneath an alley adjacent to retail stores. There was a long delay in restoring a bank to service because of the need for airing out the vault sufficiently to permit the men to enter and clean up the damage. Many complaints were registered by adjacent store proprietors, and one could not help but wish for some dry-type or other transformer which would not be subject to similar damage. In fact, the solution to a problem of this nature may well be the use of a sealed dry-type transformer which has no combustible material in its makeup.

The use of an insulating material which can be subjected to higher temperatures such as class *H* should permit an over-all smaller transformer. Large numbers of vaults exist with fixed hatchways in their tops which will not permit passage of transformers of over certain dimensions. A reduction in the physical dimensions of transformers with an increase in kilovolt-ampere ratings would certainly appeal to the cost-conscious utility group. This is especially true today, as statistics indicate that electric loads have grown and it is generally predicted that future consumption will be even greater.

We are contemplating the conversion of some 4-kv network vaults to 13-kv network. Transformers of correct size both electrically and physically will permit the use of existing hatchways, eliminating the need for rebuilding transformer manhole tops and thereby allowing the conversion to be completed with minimum cost.

The author has presented a valuable and timely paper based on tests and practical experience. His test results are very interesting and quite comprehensive. The rugged tests on the 15-kv models are evidence that much progress has been made toward the production of a safer 15-kv dry-type transformer which should be gratifying to those utility men who work with network transformers. With continued research, production costs should be reduced and the dry-type transformer will rightfully take its place in the utility picture.

Perhaps newer types of insulation will be developed with the co-operation of the chemist and the electrical engineer which may still further reduce the physical size and still be economically practical. Perhaps gas other than nitrogen will be found for use in sealed dry-type transformers which will be even more efficient.

A. F. Phillips (Duquesne Light Company, Pittsburgh, Pa.): Mr. Manning has made a very interesting and useful contribution to the art of model testing dry-type transformers. Data on the aging of insulation are needed to demonstrate the reliability of the three groups of dry-type transformers when operating at their permissible hottest-spot limits. The test data summarized in the paper indicated that seven models, which are rated at 180 C rise (220 C total temperature), withstood 275 C for 14 days and that one model withstood 275 C for 34 days. A few tests were made at 350 C. Although it is a good start, the limited test data presented in this paper are not enough to establish the life criteria for this type of equipment. It would be desirable to increase the creepage distances so that actual failures could be obtained from which a life versus aging temperature plot could be made as the author mentions in his conclusion 5.

Data on the aging of class-*H* insulation and information on the method of calculating hottest-spot temperatures of overloaded class-*H* transformers are needed by the utilities to aid in the assignment of emergency operating ratings. Occasionally it may be necessary to operate a 220 C transformer at 275 C. It is very difficult to understand the significance of test data at temperatures over rated value if means of interpreting them in terms of per-cent load are not known. The tables in the paper list the winding currents in the models necessary to maintain the three different test temperatures, but these values cannot be translated into per-cent load on an actual transformer.

Since the author has developed the knowledge and technique of running model tests at very high temperatures, he should be encouraged to continue the work as these data are essential to the economical operation of this type of equipment.

Dr. A. A. Halacsy (I-T-E Circuit Breaker Company, Philadelphia, Pa.) The tests showed that creepage sets the limit to the voltage in dry-type transformers. Does the author think it possible and practical to build dry-type transformers for voltages higher than the 15-kv class in the light of the difficulties experienced in creepage?

W. W. Satterlee (Westinghouse Electric Corporation, Sharon, Pa.): In commenting on Mr. Manning's interesting paper, I desire to compliment the Chairman of the AIEE Working Group on Life of Materials, John L. Cantwell, for his capable guidance of the activities of the Group, and, less directly, the members of the Subgroups who have been studying the temperature classifications of insulation structures for dry-type transformers during the past few years.

Mr. Cantwell appointed the first Subgroup of four members of the Working Group in November 1952 to study the functional evaluation of insulation systems for dry-type transformers. The Subgroup agreed that there were two possible approaches to the subject: first, the testing of insulation elements, i.e., component parts for use in an insulation structure, or second, the testing of complete insulation structures as used in transformers. The first approach may be called the component method; the latter, the model method of testing.

At a later meeting this Subgroup agreed that it would work to effect a recommendation for the model method of testing to establish bench marks for temperature classes of insulation systems for dry-type transformers and the preparation of a test code for this purpose. The work of this Subgroup was completed in May 1953 with the preparation of a tentative test code, including the design of a particular model for use in laboratory testing of insulation structures. In June 1953 the Working Group agreed that the work of the Subgroup represented a step in the direction of standardization and the establishment of design codes based on model tests, because temperature limits are determined not only by the chemical structure of the insulating materials but also by the manner in which they are used in an insulation structure.

The proposed test code deals with functional testing and temperature classification rather than with the testing of components and the classification of materials. To continue this work, Mr. Cantwell appointed a second Subgroup to consider modifications of the proposed test code in accordance with suggestions of the Working Group and to set up a program for obtaining the basic data required to establish the model method of testing and the requirements of the code. Since then, members of this Subgroup have done a considerable amount of model testing of insulation structures for the purpose of establishing the workability of the proposed test code. Mr. Manning's paper represents a contributing portion of this work.

However, interpretation of the author's results is difficult. In doing this, one should keep in mind the original objective as formulated by the Subgroup. It was to give laboratory trial to the test procedure specified in the code and to the specific model recommended for the testing of a 15-kv insulation structure. It was not intended at this time to use the test code to determine the permissible operating temperature for any specific insulation structure. Due consideration of these things may help in understanding the author's results.

In the tests Mr. Manning describes, flashovers occurred in the models. Thus, if flashovers are taken as insulation failures, which is a provision of the test code, the author's results show the life of the models to be very short. For instance, at 275 C the life of group 3 transformers may be expected to run over 5 cycles of 8 to 16 days' duration instead of 3 to 4 cycles at 48 hours each.

One possible reason for the apparent short life of the models is, as the author points out, insufficient electrical clearance in the models. If so, we must acknowledge that the results of the author's tests, as related to the permissible operating temperature, are not conclusive and that additional tests designed to specifically determine the permissible operating temperature for group 3 dry-type transformers are very desirable. However, when one considers that the intended objective of the tests was to help establish the validity of the proposed test code, then the author's work constitutes a valuable addition to the entire efforts of the Subgroup. Mr. Manning deserves much credit and he is to be commended for his co-operation with the Subgroup on this overall subject.

M. L. Manning: Comments by the discussers are appreciated. A practical approach to operating problems is a necessity. In dealing with the subject, it must be remembered that data were not available for such severe temperature and humidity cycling as outlined for a test cycle in the paper for a 15-kv class silicone glass fiber insulation system. A model structure was agreed upon by the Subcommittee for laboratory trial. Numerous models must be tested in conformity with a test code, when available, to arrive at answers to all questions. The purpose of this initial paper dealing with group 3 dry-type transformers was to verify if a 15-kv class model is practical, to devise a practical test procedure, yet impose operational conditions, and to obtain helpful information for a test code by establishing a few beacon lights for possible aging temperatures. The validity of a possible test code must be established. It should be realized also that much thought and planning was required in the AIEE Working Group on Life of Materials and in the Subgroup on Functional Tests. Other members of the Subgroup studied lower temperature group 2 transformer insulation systems while the author was given the responsibility for group 3 (high temperature) insulation systems.

Of importance is the fact that only heat cleaned glass fiber base material and high temperature withstanding silicone resins and rubbers were used in my system. Unless oil and sizing is removed from glass fibers, insufficient bond strength of the resin to the fibers exists and delamination will occur at high temperatures. This fact is highly important when considering insulation systems aged in air at 275 C and 350 C. The end or failure points at such high temperature cycling are dependent upon the quality of the insulation system.

Mr. Goldberg's comments offer support to safety features desired by most operating people. Unless an insulation system considered for functional tests at high temperatures meets safety from fire and explosion hazards where human life is in danger, the system cannot be practical from a user's point of view. The insulation system described in the paper is free from volatile oils and toxicity, will not support combustion, and can be used at 220 C hottest-spot temperature in air or nitrogen. In case nitrogen leaks from a tank in a network transformer having this insulation system, load can be maintained until resealed. Conclusions that danger from fire and explosion is eliminated are verified elsewhere.[1] As Mr. Goldberg points out, by continued usage the economic picture for high temperature materials can be changed to decreased costs. A similar situation existed about 14 years ago when phenolic impregnated and bonded glass fiber materials were first introduced. Use of gases other than nitrogen to reduce dimensions of sealed transformers are under study; results are encouraging. The problems encountered by Mr. Goldberg in the application of network transformers are interesting.

Mr. Phillips emphasizes an important fact that more work is required to get possible answers to end-of-life points for insulating materials. This problem has plagued engineers for many years. For the silicone insulation system described in the paper for group 3 transformers, it is hoped that a few guideposts are established in arriving at suitable test code aging temperatures. A functional or prototype test method will assist greatly in estimating emergency temperature limits. But it must be remembered that correlation with transformers in service is necessary. Models alone cannot establish a direct relationship with transformers with respect to current density in windings, core heating, and circulatory effect of cooling by ducts. An insulation system is evaluated by a test model to give the user and manufacturer information concerning this system. Actual stresses on the insulation, both thermal and electrical, are imposed by the cycling. It is helpful to know that Mr. Phillips is in accord with the indea for continuing the work in obtaining data essential to the economical operation of transformers.

Dr. Halacsy questions the possibility of voltage creepage as setting the limit to the voltage rating of dry-type transformers. Perhaps in the models voltage creepage appeared to establish the end point but it will be recalled that the 3-inch creepage distance of the high-voltage winding to ground (end plate) was set to determine if creepage or flashover would occur. Actual 15-kv class transformers use greater creepage distances, hence the next step is to increase the distance in the models since the basic question was answered in that the barrier structure did not puncture. If certain operational characteristics such as higher impedance and dimensions are permissible, it does appear possible to build dry-type transformers higher than 15-kv class, particularly by use of perfluorocarbon gases for sealed units. Development work is proceeding in this direction.

Mr. Satterlee outlines an interesting review of the committee work in establishing the background of the paper. At a later date, the combined work of the AIEE Working Group on Life of Materials and the Subgroup will be presented. My work deals with an insulation system having a 70 C higher permissible hottest-spot winding temperature, hence the problems differ in many respects from the insulating systems studied by other members of the Subgroup.

Mr. Satterlee comments that my results are difficult to interpret in that at this time the test code was not intended to determine the permissible operating temperature for any specific insulation structure. I wish to make the point clear that no test code or bounds for aging temperature limits were in existence at the time the models were tested. The purpose of the testing was to establish the validity of requirements that might be met in formulating a test code. But we must remain practical in correlating data established by a test code with transformers in service. In this manner we can obtain better answers to insulation problems. Conclusions in the paper amplify my viewpoint. Additional tests on models will be made, utilizing increased creepage distance to obtain puncture of barrier insulation.

It is hoped this initial paper will arouse interest in obtaining good answers to end-of-life aging questions and overloads on transformer insulation systems which have been of concern to engineers for many years. Users and manufacturers of transformers must co-operate to enjoy success.

An Experimental Gas-Insulated 138-Kv Current Transformer

G. CAMILLI
FELLOW AIEE

IT IS well recognized that under special conditions the dielectric strength of some gases is superior to both liquid and solid insulation. The low dielectric loss of these gases, their self-healing qualities, and relatively low cost are outstanding characteristics which are very useful in some applications. Thus compressed Freons and sulphur hexafluoride have been used in high-voltage capacitors where low dielectric loss is essential, and in X-ray transformers where reduced dimensions and nonflammability are of primary importance. Recently, compressed fluorocompounds have also found application in the production of very high voltages for nuclear physics work.

As far as the author knows, gas-insulated apparatus has never before been built for operation on a commercial power system where the equipment may be subjected to surges and lightning voltages. An experimental 138-kv gas-insulated current transformer is described which withstood all the commercial tests both at low frequencies and impulse voltages levels as specified in the American Standards Association Standards for transformers.[1] Three types of insulating mediums are discussed, solid, liquid, and gaseous, and the reasons why gas insulation was chosen are given.

The Influence of the Insulating Medium on the Type of Construction

Since solid insulation generally has higher dielectric strength than either liquid or gaseous insulators, there is no doubt that solid insulation, either in the form of resin-impregnated fibrous material or cast synthetic resins, leads to the most compact designs. In this case, however, the complete elimination of voids is of paramount importance. Another problem which needs to be considered is the dissipation of heat under normal and overload conditions. The eyebolt design in which the solid insulation (paper) is impregnated with oil as in an oil-filled cable is a good compromise. It will be noted that in this case, Fig. 1, the high-voltage winding is enclosed in a metal shield and the solid insulation is wound over the shield. In high-voltage transformers where the thickness of the insulation is

Paper 55-12, recommended by the AIEE Transformers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted September 16, 1954; made available for printing October 28, 1954.

G. CAMILLI is with the General Electric Company, Pittsfield, Mass.

The author acknowledges with grateful appreciation the help given by C. D. Geisler in the preparation of this paper.

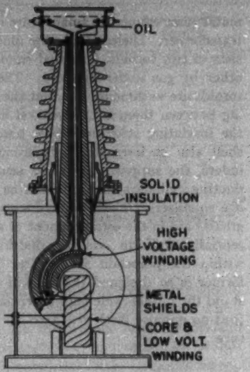

Fig. 1. Cross-sectional view of the conventional high-voltage current transformer

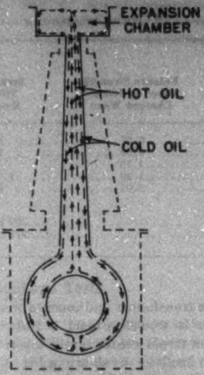

Fig. 2. Cooling diagram of the conventional high-voltage current transformer

Fig. 4. Internal view of the 138-kv gas-insulated current transformer showing the low-voltage shield and high-voltage shield

appreciable, there will be little or no heat dissipation through the solid insulation. The cooling is provided by the circulation of the oil existing between the shield and the high-voltage winding, as shown in Fig. 2.

When solid insulation with no trace of liquid is used, the casting material encloses only the low-loss dissipating elements of the current transformer. In a current transformer, most of the heating is produced by the high-voltage winding inasmuch as the low voltage winding carries only 5 amperes at full rated primary current, and the iron core operating at very low flux densities (ordinarily at less than 1,000 gausses) has little loss to dissipate.

Current transformers in which the main insulation consists exclusively of an insulating liquid have not been looked at very favorably by those familiar with high-voltage phenomena. The main objection being that particles such as lint, or bits of paper, especially if wet, may be attracted into the regions of high dielectric stresses and produce internal flashover. Therefore, it has been a generally accepted parctice to introduce between the high- and low-voltage windings some sort of an insulating barrier, or barriers, with a total thickness so proportioned that in the case of momentary complete breakdown of the liquid the solid insulation by itself is sufficient to withstand the impressed voltage for a very short time. Under some conditions, the barrier actually stops streamers and spittings, thereby preventing full spark-over. A streamer hitting a barrier in a liquid splashes a short distance and is quenched.

In the case of a gas-insulated transformer with no forced circulation, there will be no extraneous or foreign material which may float in the insulating medium; therefore, there will be no need for any discontinuity in the insulating structure. Furthermore, a streamer hitting a barrier in gas is possibly more self-perpetuating because of the longer free-path distances between molecules. It should also be recognized that owing to the wide difference between the permittivities of solids and gases the corona-starting voltage, for a given total dielectric distance, will be lowered by the introduction of a barrier into the gap.

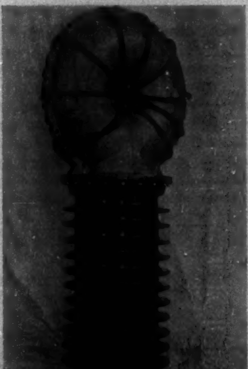

Fig. 3. External view of the 138-kv gas-insulated current transformer

It might be argued that in case of failure in the all-gas insulating structure the low-voltage winding may be brought up to the voltage level of the high-voltage winding. This difficulty can be easily overcome by enclosing the low-voltage

10		371 kv rms		

winding within a shield which is solidly connected to ground. It is interesting to note that while in a conventional liquid-insulated transformer the insulation strength is mainly dependent upon the thickness and quality of the insulating material, in a gas transformer a third variable, pressure, is introduced with a subsequent increase in the flexibility of the insulating structure.

Among the various gases, the fluorogases are of particular interest in high-voltage applications because of their generally inert character and high dielectric strength.[3] The fluorogases of most interest are the Freons, sulphur hexafluoride, and the fully-fluorinated compounds such as C_2F_8.

Characteristics of the Gas Used in This Experimental Transformer

In this experimental transformer, sulphur hexafluoride was selected as the gas which has the most advantageous characteristics.[4,5] Under normal service conditions, SF_6 is inert and nonflammable and produces no harmful effects on personnel if it accidentally escapes from the apparatus.

The density of SF_6 is approximately five times that of air while its specific heat, at 55 degrees centigrade, is 70 per cent that of air. It follows that, since the product of the specific weight and the specific heat of SF_6 is higher than that of air, SF_6 has a higher total heat absorption than air. One pound of SF_6 at atmospheric pressure fills approximately 2 cubic feet (19 gallons). At the present rate of production, the price per gallon of SF_6 at atmospheric pressure is less than one-half that of standard transformer oil.

Description of the Gas-Insulated Transformer

The transformer is of the porcelain clad type. The most striking feature is that the high-voltage winding is external to the transformer and consists of a cable which is wound around a hollow aluminum toroid located on the top of a porcelain insulator, as shown in Fig. 3. The toroid is connected to one terminal of the high-voltage winding and encloses the core, the low-voltage winding, and a grounded toroidal shield for the low-voltage winding, as shown in Figs. 4 and 5.

Both the high-voltage and low-voltage toroidal shields are split into two sections, the low-voltage shield being supported by the secondary winding and the core. The latter is held up in position by a metal stem connected to the base of the transformer. Dielectrically the unit consists of two toroids, insulated from each other by gas under pressure. The two toroids are so dimensioned that the spacing between them is the weakest link in the insulating structure. The porcelain shell also encloses three insulating cylinders, the supports for three semiconducting cylinders that function as voltage equalizers. These voltage equalizers greatly aid in the establishment of an essentially uniform voltage distribution within the porcelain shell. The transformer is so designed that it will withstand the full 60-cycle high-potential test (but no impulse test) with zero gas pressure.

Dielectric Tests

The experimental unit has been tested at both 60 cycles and impulse voltages, with the results shown in Table I. It should be noted that in accordance with American Standards Association Standards[1] the required 1-minute 60-cycle test for 138-kv transformer winding should be 277 kv, while the 1-minute 60-cycle with-

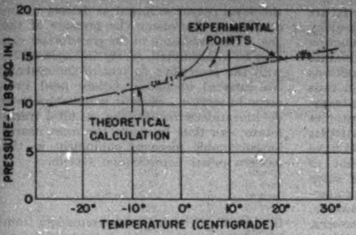

Fig. 6. Internal pressure versus temperature of the 138-kv gas-insulated current transformer

stand voltage for a 138-kv bushing should be 335 kv. Also, the high-voltage winding of the transformer should withstand impulse tests to ground of 650 kv (standard full wave) and 750 kv (chopped wave).

It is interesting to note that during the dielectric tests a transformer of this type can be repeatedly spark-discharged internally without any apparent damage. Therefore, by a few trials at various working pressures, the insulation strength can be placed, within limits, at the most desirable level This is a unique feature of the gas-insulated transformer which cannot be conveniently duplicated by the conventional liquid-filled transformers. From the foregoing test results, it appears that a working pressure of 10 pounds per square inch gauge, at 25 degrees centigrade, is sufficient to meet the various dielectric tests required.

Accuracy Characteristics

From the standpoint of its accuracy the transformer can be thought of as essentially a through-type current transformer in which the number of turns of the primary winding can be changed to maintain a constant, predetermined number of ampere-turns. By making suitable changes in the number of high-voltage turns, and in some cases by selecting the proper low-voltage tap, any standard ratio of transformation of from 1 to 1 to 400 to 1 is obtainable. To obtain good accuracy without the use of any compensating scheme, the transformer is designed for operation at 2,000 ampere-turns. Thus, the transformer can be used for a large range of primary currents.

While it is desirable that the primary winding be evenly distributed around the circumference of the toroid, the results shown in Table II indicate that the accuracy of the transformer is not influenced by the unsymmetrical positioning of the turns. For relaying service, the current transformer has an accuracy-class rating of *10L800*.

Gas-Leakage Tests

The current transformer, which was built in the fall of 1946, has shown no appreciable leakage of gas in all these years. The unit was first filled with nitrogen about June 1, 1947. For about 4 weeks, frequent readings of temperature and gas pressure were made. At the end of that time, as no leaks had appeared, the nitrogen was replaced with sulphur hexafluoride and the unit was placed in an outdoor testing area and energized at 150 kv, 60 cycles to ground. Readings of temperature, gauge pressure, and barometric pressure were made each day until September, 1948, and thereafter once each week. Fig. 6 shows that the relationship between pressure and temperature readings checks very closely with theoretical calculations, indicating that the unit can indeed be made gas-tight by using ordinary rubber gaskets. Samples of the gas obtained after the transformer was continuously energized for 3 years contained no decomposition products.

Tap for Potential Measurements

A capacitance tap can be readily added to a gas-insulated transformer. Since the dielectric constant of the gas does not change appreciably with temperature, it appears that a capacitance divider could be built which would be more accurate than the conventional apparatus which utilizes liquid-filled components.

Explosion Characteristics of the Gas-Insulated Transformer

When a failure occurs, the pressure developed in a gas-filled transformer is only a fraction of that developed in a liquid-filled unit. The pressure from the arcing of sulphur hexafluoride develops from thermal excitation of the gas rather than from the formation of a large amount of dissociation products. As mentioned, before, under breakdown conditions, the arc occurs between the two torodial shields. The pressure of a moderate cushion of gas located at the arc prevents any very rapid build-up of pressure throughout the remainder of the transformer and, therefore, it would be feasible to relieve the pressure by means of a relief diaphragm and so prevent it from reaching dangerous values.

Conclusions

An experimental current transformer has been developed in which the main insulation consists exclusively of a fluorinated gas under pressure. It appears that this type of transformer has several advantages over the conventional liquid-filled unit, especially for voltages higher than 115 kv. They weigh considerably less than comparable liquid-filled units. These units can be operated in any position; they have unlimited ratio adjustment; and their inherent insulation strength can be readily determined. While designed to operate at 10 pounds per square inch gauge, under certain conditions they can operate satisfactorily with the gas at atmospheric pressure.

Discussion

H. R. Lucas (Canadian General Electric Company, Ltd., Toronto, Ont., Canada): Much has been said of the advantages of automation in removing the load of drudgery from human shoulders. Any development which will remove an onerous, time-consuming, and monotonous operation from a manufactured article can be classified along with automation as an ultimate benefit to humanity. Of such a nature is the development described.

In a conventional design of an oil-filled current transformer, the high-voltage coil must be insulated by taping on solid insulation which is subsequently dried and oil-impregnated under high vacuum and with great difficulty. Because of the irregular shape of the coil, it is impractical to apply the tape by machine. The work must therefore be done by hand. Several hundred pounds of tape may be applied to a single coil in a monotonous wrapping operation which may take 100 hours or more to complete. The drying and oil treatment of the masses of insulation so applied takes days and even weeks in the larger sizes of oil-filled transformers.

In contrast, the gas-filled transformer, having its insulation inserted by the mere opening of a valve, takes no longer to apply insulation to than the time required to inflate an automobile tire. Also, having a negligible quantity of hygroscopic insulation the problem of treatment to remove moisture is practically eliminated, and the time required for this operation is reduced from many days to a few hours.

From a design engineer's point of view, the desirability of knowing the exact margin of safety attained in his design must be tempered by the cost of finding out the breakdown level of an expensive sample or prototype. Limited numbers of tests are therefore performed, and fairly healthy margins of safety are used on production designs to allow for manufacturing variables and experience factor. Under no conditions can the actual breakdown level, and thus the factor of safety, of the particular transformers built for shipment to the customer be found by test. Tests done on samples show the factor of safety which would have been obtained, if the same amount of identical insulation is applied the same way to an identical structure in the production design. Variations do occur, however, in the materials themselves, the processes, and in the human element. For these reasons no manufacturer will willingly exceed the recognized insulation test levels on a transformer built for a customer, even though he knows the margin of safety in his design was 30 or 40 per cent on the prototype samples.

With the gas-filled transformer this objection is removed. Not only can the actual insulation puncture or flashover level be determined by nondestructive testing but this level can be adjusted as desired by increasing or decreasing the pressure of the gas. The insulation in the transformer can thus be co-ordinated, surely and accurately, with the protective devices of the system. No internal insulation failure need ever occur in service. Since it is not subject to deterioration with age, the gas-filled transformer can thus be made the most nearly indestructable piece of equipment in the modern power transmission system.

G. Camilli: The favorable comments from Mr. Lucas are gratifying and are very much appreciated by the author. While the 138-kv current transformer described in this paper was insulated with sulfurhexafluoride, it should be noted that new gases are being developed for electrical purposes. It is possible that some of them may have superior characteristics in which case the size of the transformer can be reduced without impairing its operating characteristics.

Results of High-Current Tests on 161-Kv Disconnecting Switches

A. M. McNERNEY
ASSOCIATE MEMBER AIEE

THE trend toward heavy power concentrations, starting in the Tennessee Valley Authority (TVA) area in 1951, led to the development of 10,000-megavolt-ampere circuit breakers for 161-kv service, with anticipation of 15,000-megavolt-ampere interrupting ratings.[1] At the same time, continuous-current ratings up to 1,600 amperes were required. The industry, however, had failed to develop disconnecting switches to meet the same service.

To stimulate the development of new designs of switches, or modifications of existing designs, the TVA announced in May 1952 a program of high-current testing of disconnecting switches. A momentary current of 62,000 amperes rms was specified to co-ordinate the switch capability with the circuit-breaker rating.[1] Manufacturers were invited to submit samples to meet the increased requirements. No limit was placed on the number of variations in design which could be submitted for test. The conditions applying to the tests and the testing equipment are described by Gostin.[2] The tests and test results on switches submitted by manufacturers as well as on old switches taken out of service are described in this paper.

Scope of Tests

The announced scope of tests to be performed on new 1,200- and 1,600-ampere switches submitted by manufacturers was as follows:

1. 60-cycle momentary current test at 62,000 amperes rms in six successive shots, each not more than of 10-cycle duration. Time intervals between the first three shots, approximately 20 cycles; between third and fourth shot, approximately 10 minutes; between the last three shots, approximately 20 cycles. (While 20 cycles was specified as the interval between test shots, the limitations of the equipment were such that the interval actually was about 70 cycles.)
2. Temperature test at continuous-current rating of switch.
3. Momentary current test at higher current values.

Momentary current and temperature tests were also made on a number of old switches which were removed from service at locations on the system where the duty had become critical. These tests were designed to determine the actual capabilities of these old switches. Special tests were made on certain new and old switches in an attempt to determine the effect of contact pressures, contact coatings, and other features on the momentary current capabilities.

Summary of Switches Tested

The following is a summation of the switches subjected to high-current tests. New switches submitted by manufactures: 11 of 1,600 amperes and 12 of

Notes: *Switch sent to temperature test; see Tables II and III.
(a) Total number of contact fingers on jaw end.
(b) Rms value of first half-cycle.
(c) Blade reinforced with steel inner liner for stiffness. IPS stands for iron pipe size. (This also applies for Tables II, III, IV, and VI.)
(d) Oscillogram defective.
(e) Standard design, not modified for tests.
(f) First switch tested had an external hook for locking blade in position (removed on subsequent tests).

1,200 amperes. Miscellaneous switches removed from service on the TVA system: 2 of 1200 amperes, 4 of 600 amperes.

A total of 374 test shots was made on new switches submitted by manufacturers and the results are summarized as follows:

Switches	Current Rating, Amperes	
	1,200	1,600
Destroyed	2	1
Moderately damaged	1	1
Slightly damaged	4	2
Not damaged	9	7

Types of New Switches Tested

All except one of the switches submitted by manufacturers were of the rotating-blade, high-pressure contact type. The one exception was a push-pull type with multiple fingers forming the jaw.

The 1,200-ampere standard designs had single or multiple contacts on the jaw end. The conformation followed the generally used design in which the contacts form a right-angle offset between the blade and the terminal pad. This conformation is referred to as offset contacts herein. About half of the designs had bosses on the contacts or crimped conformation or even separate latches to provide means of counteracting the magnetic forces tending to blow the blade out of the contacts at high currents.

A majority of the makers offered modified designs aimed at eliminating, mitigating, or resisting the blade blowout effect. These included such features as reinforced blades, increased number of contacts on the jaws, or modified contact conformation such as in-line conformation (i.e., the blade, contacts, and terminal pads are in a straight line), or reverse-loop contacts. In the latter design, the conformation is offset but the contact forms a loop and utilizes the magnetic effect of the increased current to apply more pressure. The 1,600-ampere ratings generally incorporated the same contact designs as the modified 1,200-ampere designs. Blades necessarily were larger and the extra stiffness added to their ability to resist the blade blowout effect. Contact pressure was applied in some cases by mounting the contact fingers on beryllium straps; in others by backup springs. All except one had silver-to-silver or copper-to-silver contacts. The one exception was a copper-to-beryllium contact.

Determination of Test Current

A tracing of a typical oscillogram of a high-current test shot is shown in Fig. 1. All current values shown in the tables are amperes rms of the first half-cycle determined in accordance with AIEE Standard No. 22.[2]

Momentary Current Tests on New Switches

The most significant of the momentary current tests on switches as submitted by manufacturers are shown in Table I. Many of the test shots are omitted because it is felt that they do not contribute enough to this paper.

In making the tests on these switches as well as on subsequent tests, a single pole was mounted and adjusted on the test structure. The blade was then opened and closed, using the operating lever on the rotating insulator stack, and the lever was then wired in place to simulate the locking action normally obtained from the operating mechanism.

For the sake of simplicity, no attempt is made to tabulate the various jaw contact designs except for their general physical conformation. Rear, or hinge, contacts also are not tabulated. On the majority of the switches, the hinge contacts were duplicates of the front contacts. One make used flexible shunts. Some used nonbreak shunts or contacts. The hinge contacts obviously were not subjected to the same forces as the jaw contacts and only one make sustained damage at that location.

It will be noted from the tables that a considerable range in current was obtained in shots of the same series. While the offset of the test current delivered by the test equipment was not as consistent as expected,[2] the transient factor (ratio of rms of first loop to rms of steady state), however, averaged 1.48 for all shots and was in excess of 1.5 for the maximum shots listed in the tables. Judgment of the performance of the switches was, of course, based upon the maximum shots.

In several cases, more than the announced number of test shots was made on a particular switch. In some instances this was because of adjusting for better current or better offset values. In other instances, notably switches *C-2*, *C-4*, and *D-1*, switches were returned from the temperature test and retested in an attempt to destroy them either by higher currents or by repeated test shots.

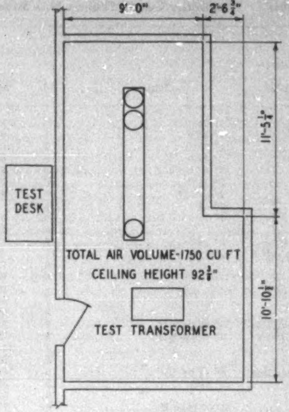

Fig. 2. Layout of temperature test room

Except for switches *H-1* and *H-2*, all damage sustained was on the jaw contacts, and the test results described in the last column of Table I refer to that location. The terms in the test results tabulation refer to the condition of the contacts when examined after each series of shots. "Minor pitting" or "slight burns" indicate the start of welding or burning action not sufficient to affect the operation or continuous-current capacity of the switch. Line burns or welding were sufficient to affect the switch, but it could still be made operative by redressing the contacts.

Temperature Tests

In making the temperature tests on the different makes and designs of switches, it was desired to obtain exactly comparative data. Existing standards are vague, at best, as to the conditions under which such tests should be made. It is well known what effect a draft within a room, or a slight cross-breeze if outdoors, will have on test temperatures of equipment.

The electric equipment for the temperature tests are described by Gostin.[3] To obtain identical conditions for each switch, the switches were tested in an interior room, the dimensions of which are shown in Fig. 2, and closed off by the only access door. The loading transformer was located in the room, and thermocouple leads and current transformer leads were run to a test desk located outside the room. The only time the room was entered during a test run was to check the ambient temperature from mercury thermometers located above and to each side of the test switch. The results of the temperature tests on new switches are shown in Tables II and III. Because of the variations in switch designs, and to simplify the tabulation, only comparative points are listed. For multiple points such as contacts, shunts, etc., the observed range is shown.

Temperature tests were made at rated current and, unless otherwise noted in the tabulation, on the same switch which had been subjected to the momentary current tests. Temperature tests also were made at rated current and at other values on two of the older switches removed from service. The results of these tests are shown in Table IV.

In all cases, switch types and numbers shown on the tables of temperature tests are the same as shown on the high-current tests. Particular attention is called to the temperature tests on switch *F 1*; see Table II. The final temperature of the center of the 1 1/2-inch extra-heavy blade was much lower than expected, especially under the conditions of the test. Investigation disclosed that the blade was heavily coated with a smooth clear lacquer, presumably for appearance. The test was rerun with the lacquer re-

moved and the results show how the lacquer affected the temperature readings.

Tests on Old Switches Removed from Service

Old switches removed from service and subjected to momentary current and temperature tests were of the following types:

1. Rotating blade, high-pressure contact type, two offset contacts per side on single beryllium strap. Installed 1 year prior to test.

2. Rotating blade, high-pressure contact type, one cast beryllium offset contact per side. Installed about 10 years prior to test.

3. Area contact, push-pull type, pressure-applied to floating contact shoe by fixed spring. Installed about 12 years prior to test.

4(a). Area-contact type with auxiliary device for applying pressure to floating contact shoes. Installed about 14 years prior to test.

4(b). Same as 4(a) except with pressure-applying device removed.

5. Multiple shoe contacts, push-pull type, pressure-applied to floating contact shoes by fixed springs. Installed about 15 years prior to test.

6. Rotating blade, high-pressure contact type, one cast beryllium U-shaped contact. Installed about 7 years prior to test.

These switches had been removed from hydro stations or remote switching stations and had, therefore, not been subjected to contaminated atmosphere.

The results of the tests on switches 1 to 5 are shown in Table V. The designations *A*, *B*, and *C* under switch 2 are for tests on each of the three poles of switch 2. As in the case of the tests on new switches, all damage sustained was on the jaw end and the test results refer to that location. The results of the tests on switch 6 are shown under switch *J-1* in Table VI.

Table V. Momentary Current Tests on Old Switches Removed from Service

Switch No.	Continuous-Current Rating, Amperes	Blade	Test Shots No.	Rms Amperes(a) Maximum	Rms Amperes(a) Minimum	Test Results

(b) Switch as received had auxiliary contact pressure applying device.
(c) Contact-pressure applying device adjusted and locked in place.
(d) Contact-pressure applying device made inoperative.

Special Tests

Tests were made on several makes and ratings of new and old switches to determine the effect of contact pressure, contact coatings (such as graphite), and special features such as reinforced blades or increased number of contact fingers. These tests are tabulated in Table VI.

It will be noted that some tests from Table I are repeated in Table VI because modifications were made on switches originally tested "as received," and it seems desirable to repeat the test data for direct comparison. The switch *J* was an old switch, described in item 6 in the section entitled "Tests on Old Switches Removed from Service." Test

Table VI. Special Tests

J-12	600	6	offset	55	none	2" type *K*	3	62,500	52,400	slight transfer of metal
							3	61,500	57,300	slight transfer of metal

Notes: (a) Total number of contact fingers on jaw end.
(b) Rms value of first half-cycle.
(c) Blade reinforced with steel inner tube for stiffness.
(d) External latch to restrict blade movement.
(e) Estimated. Oscillograph did not record.
(f) External latch removed.

J-1, see Table VI, was on the switch as removed. Subsequent tests, *J-10*, *J-11*, and *J-12* on that make, were on various combinations of replacement blade tips and multiple contacts furnished by the original manufacturer. The test results refer to the conditions at the jaw-end contacts because, as also noted in the section entitled "Momentary Current Tests on New Switches," all damage sustained was at that location. Blade movement in all cases refers to the total displacement of the blade tip.

Inspection After Tests

Upon completion of the testing program, all the switches tested were assembled at one location for a general inspection and comparison of design features. It was thought that the inspection might disclose some explanation of apparently inconsistent results in the tests.

It is evident that over- or underadjustment of the blade-operating linkage can greatly affect the blowout effect at the contacts. Sloppy fits in some linkages result in lack of control of the blade to such an extent that the blade tip will orient itself in different positions during successive opening and closing operations. Any play in the linkage also minimizes or eliminates any holding effect in the hinge end which might help to counteract the blade blowout effect.

Both the test results and the general inspection leave a doubt as to the effectiveness or desirability of blade-latching devices such as bosses or crimps on the contacts or external latches unless they are absolutely necessary for proper blade action, especially under icing conditions. Otherwise, it appears that such features constitute too much of a hazard to proper blade-closing action.

Conclusions

It is dangerous to draw definite conclusions from a limited series of tests. Even though a total of 374 test shots was made, they were spread over so many makes and types that, with a few exceptions, each received only a limited amount of testing. Factors such as variations in magnitude and asymmetry of the test current, or variations in blade adjustment or blade position, could be eliminated only by a long series of tests on each switch. However, it is believed that the high-current tests were extensive enough to justify the following general conclusions:

1. Single contacts are inadequate for high-current ratings.
2. Standard 1,200-ampere switches can be rerated to a 62,000-ampere momentary rating by one of the following modifications: reinforcing the blades to obtain greater strength in resisting the blade blowout effect; increasing the number of contacts; adopting an in-line arrangement of blade, contacts, and terminal pad; or using a reverse-loop contact construction.
3. Older type of switches, using the push-pull blade action and single, floating, area contact fingers, have higher short-time capability than the standards in effect at the time of their manufacture, as shown by the tests on switches 3, 4(a), and 5.

The temperature tests, even under the reasonably exact conditions provided, show some inconsistency especially at the center of blade of various makes utilizing the same size blade. The inaccuracies inherent in the thermocouples, differences in their mounting, errors in reading them, differences in conditions of blade surfaces and end drainage all contribute. However, the differences in the tests were within reasonable limits as compared with the gross differences between these tests and factory tests on identical switches. Standards that include exact conditions under which temperature tests at the factory are to be made, and exact conditions for preparation of the sample under test, seem definitely to be needed.

Discussion

T. E. Curtis (A. B. Chance Company, Centralia, Mo.): The high-current and temperature rise tests on 161-kv disconnecting switches performed by TVA in 1952 were very worth-while and certainly made a material contribution to the industry. I helped design some of the equipment tested and I was privileged to witness some of the tests. Some specific contributions for industry are as follows.

The attention of manufacturers of disconnecting switches was focused on the need for high-current, short-time ratings on disconnecting switches of transmission voltage ratings in considerable excess of the ratings available prior to the tests. The ever-increasing short-circuit capacity of transmission networks gave rise to this requirement. The final result is that many manufacturers now have switches which do an excellent job of withstanding short-time high currents of magnitudes greatly in excess of what was considered necessary a few years ago and an additional new series of short-time current ratings has been established for disconnecting switches by the National Electrical Manufacturers Association (NEMA) Standard *SG6-1954*.[1]

In conjunction with its test program, TVA provided a facility where short-time currents in excess of 100,000 amperes could be obtained. A facility providing test currents of such magnitude had not been available to most manufacturers up to that time, and the information gained by the manufacturers was of inestimable value in determining the final design for switches of the new short-time current ratings.

The study and tests pointed out the weakness in the then existing standards for conducting temperature rise tests on disconnecting switches and have resulted in a revision of these standards to call for better controlled conditions. We feel that the method of conducting temperature rise tests used by TVA was not entirely related to service conditions and that requirements were unduly severe. However, we are in agreement with the present NEMA Standards which, in part, adopt some of the ideas of Mr. McNerney and other TVA engineers.

REFERENCE

1. POWER SWITCHING EQUIPMENT. *NEMA Standard SG6-1954*, National Electrical Manufacturers Association, New York, N. Y., 1954.

A. H. Powell (General Electric Company, Philadelphia, Pa.): The author and his associates undertook and successfully completed a program of major proportions when they made momentary and heat rise tests on a large number of switches from various manufacturers. The results, as would be expected, varied considerably and without knowing more about the particular configuration of each switch than could be included in the relatively meager information in the tables it is rather difficult to note any particular trends as far as the most suitable type of contact or method of switch blade operation is concerned. However, it was apparent, although not expressly stated, that essentially all the switches met the values which are specified in avialable industry standards quite well.

For example, Table II giving the temperature rise tests on various new 1,200-ampere switches showed that with the exception of one switch the temperature rises were all below the 30-degree maximum permitted by the standards. The author states, and quite correctly, that a very satisfactory set of test conditions was present and that differences throughout the tests were within very reasonable limits but the facts do not seem to bear out the statement that there were gross differences between the results obtained by the author and those made in the factories. It is assumed that the switches in the factory all met the 30-degree rise limit and the tests which the author made confirmed the fact that the switches apparently met this limit.

The same condition seems to be true with the momentary test. There was generally no damage such as severe pitting or welding of the switch contacts when they were subjected to their normal values as listed in the NEMA standards. These standards, until changed in 1954 by NEMA *SG6-1954*, required that a 1,200-ampere switch pass a momentary current of 40,000 amperes and a 4-second current of 25,000 amperes without damage which might affect its current-carrying ability. All of the 1,200-ampere switches shown in Table I appear to meet this requirement. More recent changes in the NEMA standard provided an additional rating for 46, 69, 115, and 161 kv, 1,200-amperes switches consisting of a momentary value of 61,000 amperes. Apparently the various switches submitted for the author's tests were designed on this basis, for the results indicate that even at the higher value the various switches did not have particular trouble.

The results of momentary tests on some of the old switches which were removed after a number of years' service were very interesting. These old and weathered switches apparently met the ratings existing at the time the switches were built quite successfully and in fact came very close to meeting up-to-date ratings which are in general above the older requirements. Temperature rise tests also indicated that the older switches were well designed.

As a general statement, it can be said that while it is certainly very worth while to check on the quality of the products that are being used in electric systems today, such as the disconnecting switches described in this paper, it should also be emphasized that switches, like practically every other device and product, are made to some industry standards. The reputable manufacturer designs and exhaustively tests the product so as to meet these standards and whatever is designed into the device in the way of excessive material, etc., is done to insure compliance with the standards in normal manufacturing routines. Obviously the amount of excess capacity included in a design by the various manufacturers will vary considerably and may not be an indication of which device is the most suitable but could very well be based on the availability or lack of suitable testing equipment and experience with the designs over years of service.

Mr. McNerney's conclusion that more comprehensive standards are needed which will specify how temperature tests are to be made is a good one. The same comment could well be made for momentary and short-time tests. However, the conclusion that standard 1,200-amperes switches can be rerated to a higher value, especially if certain modifications are made, seems to be questionable for if the switches are made to a certain standard there is no justification for expecting them to meet greater values by making minor changes in the switch design.

S. C. Killian (Delta-Star Electric Division, H. K. Porter Company, Inc., Chicago, Ill.): The tests described in this paper are very complete and the author and his associates are to be complimented on their courage in undertaking a task that was not only exceptionally large but involved many problems in setup and procedure. The paper must necessarily be of a general nature because each manufacturer's switch is not discussed by name. The author's deductions and conclusions are important and it is likely that the entire industry benefited from these tests.

One of the most significant conclusions of the paper deals with straight-line contacts. It is interesting to follow the evolution of this contact. In 1941 my company built and patented the first switches employing a rotating blade and straight-line contacts. These were 4,000- and 5,000-ampere switches and the contact design was actually ahead of its time. The switch voltage was only 23 kv and, even though the switches were tested at 120,000 amperes, the short length of the blade and its tremendous strength precluded any blade movement.

The straight-line contact feature then was only an added safety factor. However, as soon as TVA and other operating companies began to talk of short-time currents in excess of 60,000 amperes on switches involving 6-foot 0-inch long blades this straight-line contact became a necessity. All straight-line contact design for outdoor switches is now based on similar thinking.

From the foregoing we do not intend to convey the impression that the offset or angular contact is faulty. Many switches with this type of contact satisfactorily passed these tests. As the author points out, and it bears repeating, when using angular contacts the blade must embody sufficient strength and its mounting must be sturdy and not subject to "backing up" by taking loose play out of driving links, levers, and knuckles in the live mechanism, when the blade is loaded under fault conditions.

We are pleased to see that while the author states, "About half of the designs had bosses on the contacts or crimped conformation or even separate latches to provide means of counteracting the magnetic forces tending to blow the blade out of the contacts at high currents," he concludes that, "Both the test results and the general inspection leave a doubt as to the effectiveness or desirability of blade-latching devices such as bosses or crimps on the contacts or external latches unless they are absolutely necessary for proper blade action especially under icing conditions. Otherwise, it appears that such features constitute too much of a hazard to proper blade-closing action." We feel this point is well made and that the blade should be fully controlled from the hinge and not even depend on a contact stop for its correct motions and positions, much less on bosses or latches. Those utilities which operate in sleet and ice belts can testify to the difficulty of operation on device-free switches. To put bosses and latches at the crucial contact positions would intensify this ice difficulty many-fold.

The tests on the old switches are of special interest and it is pleasing to the manufacturers to know that switches we built 10 to 15 years ago will still carry current in excess of that for which they were originally guaranteed. However, in order that there be no misunderstanding, it should be pointed out again that, "These switches had been removed from hydro stations or remote switching stations and had therefore not been subjected to contaminated atmospheres." We can be certain that had the contacts of these switches been severely contaminated the results would have been much poorer.

T. A. Burdeshaw (Southern States Equipment Corporation, Hampton, Ga.): Users as well as manufacturers of air switches are indebted to Mr. McNerney and his associates for their work in staging so comprehensive a series of tests and for the excellent exposition given. The scope of Mr. McNerney's paper is very broad, so I shall confine my discussion to a small segment of it. In particular, I shall discuss elemental considerations in studying contact behavior under momentary currents of a relatively high order. This discussion qualifies to a degree conclusions 1 and 2.

Contact failure can be attributed to excessive heat generated by one or more of the following.

1. Resistance heating of the contact bodies. In testing air switches under momentary currents this cause can be eliminated from consideration. If contact members are adequate for load currents for protracted periods of time they cannot generate melting temperatures in the brief period of a momentary test.

2. Heating at the contact surfaces from film resistance. This is a more likely cause of failure at high current. Obviously, high film resistance can result in practically instantaneous temperature rise to the melting point of contact material and failure occurs. In testing new switches or old switches with clean contacts this type of failure is not too prevalent. However, tests of old switches with contacts not cleaned shows a marked increase in the rate of failure from film resistance.

Various methods have been employed to minimize the possibility of contact deterioration from film formation. Sliding or wiping engagement of contacts results in some cleaning. Extremely high contact pressures have been employed to cut through the film.

The use of silver is relatively extensive and results in a slower rate of film formation. At the same time the film formed is softer and is more easily broken down by engagement under pressure.

3. Separation of contacts. Separation of contacts during current flow is found to be a prevalent cause of failure during momentary high current tests. Two types of separation occur, both caused by magnetic forces generated by the current flow.

a. The first type, referred to as blade blowout, results in the movement of the blade in an opening arc. It may move only a minute amount or may move completely out of engagement, depending upon the force of the magnetic field as related to the blade restraining force. The use of multiple contacts does not affect the forces producing this movement. The use of a reinforced blade increases its ability to resist blowout and therefore increases the amplitude of current necessary to move the contact. Adopting a true in-line construction eliminates the blowout force. However, some so-called in-line designs actually utilize offset contacts. Reverse loop contacts change the direction of force from the magnetic field so that it acts to force the blade further closed rather than open. A position stop prevents movement in that direction so the blade remains stationary.

b. The second type of separation results from magnetic forces acting upon the contact members to push them away from the blade. These forces under some value of current exceed the force of spring pressure and the contact opens and is damaged by arc heat. Reinforcing the blades does nothing to alleviate this condition. Increasing the number of contacts permits of greater short-circuit capacity by dividing the current among several members. Obviously, an infinite current can be carried by an infinite number of contacts. The in-line arrangement in most constructions minimizes but does not eliminate contact separation. Even they have lateral offsets in the current path resulting in magnetic separation at some value of current. Reverse loop contacts utilize the magnetic field to cancel the force working to relieve contact pressure. The result is that contacts do not separate at any value of current. With this arrangement the ability of a clean contact to withstand high momentary current is limited by the cross section melting characteristics of the contact member.

It is also of interest to note that switch *F-1* shown in Table II operated at a higher temperature after removal of the lacquer coating from the blade than had been the case when coated with lacquer. In order to show the effects of surface coatings on conducting tubing we recently made a temperature rise test on a piece of $^3/_4$-inch IPS tubing under several conditions with the following results. The tubing as received from the mill in a new condition slightly oxidized and with a temperature rise of 21 degrees centigrade (C) above an ambient of 27 C was noted. With the tubing burnished a temperature rise of 25 C above an ambient of 30 C was noted. The burnished tubing was coated with clear lacquer and a temperature rise of 20 C above an ambient of 29 C was noted. The tubing was again cleaned and a coat of lamp black was applied. The temperature rise noted in this case was 16 C above an ambient of 30 C. Again the tubing was cleaned and a coating of red Glyptal was applied and allowed to dry. Under this condition a temperature rise of 15 C above an ambient of 29 C was noted.

Lester C. Hart (Hi-Voltage Equipment Company, Cleveland, Ohio): Presentation of the result of high-current tests on disconnecting switches will be appreciated by the electric power industry, which must contend with higher fault currents than were considered when many important stations on the system were built. Anyone who was present during the tests must have been impressed with the planning and organizational work necessary to conduct them. In addition to determining what the switches would safely withstand, the tests showed the value of some elements of design.

With high currents powerful magnetic forces are developed. These magnetic forces can be used to increase the short-time current capacity of a switch. This is accomplished by providing a straight-line current path from the terminal through the contacts and the switch blade, and by making a compact contact assembly with the contact fingers or shoes close together so that the magnetic field encircling them will increase contact pressure to many times normal, thus clamping all parts as one rigid structure. Motion between current exchange surfaces, even slight vibration, appears to result in arcing. The greater the current the more pronounced is the burning.

Some of the switches tested are designed to resist the magnetic forces by mechanical means. As long as these means are maintained effective the switches safely withstand high currents.

Mr. McNerney comments on existing standards for temperature tests. The industry does not have a satisfactory standard for testing outdoor switches. Such a standard which gives consideration to normal operating conditions is needed. The best switch is a careful balance of all elements of design. Under existing vague standards, a sacrifice in one or more elements is often made to meet a test condition that is never experienced in service.

Arem Foti and **J. B. Owens** (I-T-E Circuit Breaker Company, Greensburg, Pa.): Mr. McNerney's paper was most interesting to us since our company was among those that had the privilege of submitting switches for use in the reported test program. This discussion presents a further opportunity to express our gratitude for the invitation to participate.

In the past several years there has been a pronounced growth in electric transmission and distribution systems throughout the country. Increased generating capacity and the interconnection of electric utility systems have resulted in higher system short-circuit currents. Thus, the need arose for power switching apparatus and power switching equipment capable of withstanding the short-circuit currents that could be developed.

The announcement in 1952 by TVA of a program for high-current testing of disconnecting switches was very definitely one of the stimulants that awakened the industry to the need for extending the capability of outdoor air switches. It was also instrumental in the development of the 1,600-ampere continuous current rated switches required. The response of switch manufacturers in submitting switches to meet these requirements is a tribute to the industry. It is symbolic of the spirit of co-operation with which switch manufacturers and users attempt to solve their mutual problems in dealing with new conditions and new situations that continually arise.

The need for outdoor air switches to match the momentary current ratings of circuit breakers has been given recognition, as evidenced in the October 1954 revision of NEMA Standard *SG6-1954*. The re-

Table VII. Ratings for Outdoor Air Switches

Nominal Voltage Rating, Kv	No. of Insulators	Maximum Design Voltage, Kv	Impulse Withstand, Kv	Continuous Current Rating, Amperes											
				400	600	600	1,200	1,200	1,600	2,000	2,000	3,000	4,000	5,000	6,000
				Momentary Current Rating, Thousands of Amperes*											
				20	20	40	40	61	70	70	80	100	120	160	200
				Construction Classification											
7.2 (7.5)	1	8.25	95	ABCDEFGH		ABCDEFGH		ABDEGH			ABH	AH	AH	AH	AH
14.4 (15)	1	15.5	110	ABCDEFGH		ABCDEFGH		ABDEGH			ABH	AH	AH	AH	AH
23	1	25.8	150	ABCDEFGH		ABCDEFGH		ABDEGH			ABH	AH	AH	AH

vised ratings for outdoor air switches are shown in Table VII.

An examination of the table will reveal the existence of a dual set of momentary current ratings for switches with a continuous current rating of 600 and 1,200 amperes in voltage ratings 46 kv and above. A reflection of these revised ratings in our own make of switches is shown in Fig. 3. The 20,000-ampere momentary rating per pair of contact fingers for the jaws of Fig. 3 evolved as a result of our own laboratory testing. This rating represents satisfactory performance and includes a reasonable margin of safety.

The appearance of the in-line jaw in Fig. 3 is directly attributable to the program outlined in this paper. Upon testing the 161-kv switch with a conventional jaw at increasingly higher test currents in our own laboratory prior to shipment for the TVA tests, we observed the tendency for the blade to be urged out of its jaw contacts. This blade "blow-open" effect is the result of electromagnetic forces set up by current passing through the offset current path of the conventional jaw. The in-line jaw was designed to remedy this condition, and it is a sound and proven solution. Removal of the offset path simultaneously eliminates the objectionable electromagnetic forces.

Summarizing briefly then, there did arise a need for extending the momentary current capability of outdoor air switches; recognition was given to this need in the eventual assignment of switch ratings to match circuit-breaker ratings; and finally a means of providing switches with jaw contact arrangements in accordance with the revised ratings was found. The TVA is deserving of credit for the active role it has played in this general program.

A. M. McNerney: I am deeply grateful for the interest shown in this paper as evidenced by the number of discussions and also for their generally complimentary nature. In so far as most of the discussions cover similar points, I shall consider them as a whole instead of commenting on them individually.

Several mention the new series of short-time ratings adopted by NEMA subsequent to the completion of our tests. We feel that our requirements and tests emphasized the need of such ratings and accelerated their adoption.

Comments were also made on our recommendation that definite standards be set up for conditions under which temperature tests are to be made. We are pleased that the latest edition of NEMA adopts the general features of our recommendation. Mr. Curtis states that our temperature tests were unduly severe. To that we agree, but it was only by such severe conditions that we could eliminate as many variables as possible so as to make a fair comparison between all of the makes tested. In this connection, I would like to mention Mr. Powell's comment that the paper does not bear out the statement that there were gross differences between the results obtained by me and those made in factories. That is true, the statement having been made only on the basis of what we had observed. In general, certifications of tests made in the usual large, open, and sometimes drafty test bays in factories, compared with our tests, show differences of as much as 10 degrees on parts as comparable as the center of 2-inch IPS blades.

Considerable discussion was offered on the merits of various types of contacts and our conclusions regarding means of increasing the momentary ratings of switches. Most of the switches submitted were standard designs, modified only at the jaw end. We did not try to evaluate the comparative merits of those modifications but listed those which successfully met the test. Mr. Killian's statement that angular or offset contacts require a blade of sufficient strength and a mounting sturdy enough to prevent backing up is a good one. However, multiple contacts of the angular type, if of sufficient number, seem to eliminate at least part of that problem. Whether this is due to better gripping action by the multiple contacts (for the magnetic forces are still there) we do not have sufficient data to say. However, referring to Table VI, in tests *H-1* and *J-1*, with single contacts the blade blew completely out of the jaw. The same switches with multiple contacts, tests *H-10* and *J-12*, successfully withstood the test current. We believe, although we do not have sufficient data to prove it conclusively, that multiple contacts of the angular type, even when provided with enough fingers, probably have a top limit of a 62,000-ampere rating with a reasonable added safety factor. The straight-line and reverse-loop contacts should have no difficulty matching the 15,000 megavolt-ampere 161-kv circuit-breaker rating which the industry is now developing.

Mr. Powell states that, if switches are made to a certain standard, there is no justification for expecting them to meet greater values by making minor changes in the switch design. If I understand him correctly, he questions why we should expect to find excess capacity in existing switches or increase their capacity by minor modifications. He is well justified in questioning this. However, by determining the excess capacity in existing switches or devising means of making minor modifications to increase their capacity, we were able to establish that existing switches were able to meet the short-circuit requirements at certain locations. As a result of these tests we estimate that the TVA saved in excess of $1,000,000 by not having to replace switches.

In concluding, I want to thank Mr. Burdeshaw for the tests he furnished to show the effect of various finishes and coatings on the temperature of copper tube. We are pleased to note that his test results confirm our findings on switch *F-1*, table II. This, as well as the other temperature data he furnishes, make a valuable addition to this paper.

Principles and Application of the Ultrasonic Flowmeter

S. K. WALDORF
MEMBER AIEE

NO ONE method of measurement of fluid flow has been or probably ever will be devised that will solve satisfactorily all problems as varied as the determination of flow in ocean tides, rivers, irrigation flumes, pipelines, water and sewage systems, and myriad industrial and laboratory processes. Some basic methods, however, can be used for a wide variety of applications and it is believed that the new ultrasonic flow meter is one of these. It should find many fields of usefulness in addition to the measurement of hydraulic turbine discharge, its first application, because it has no components in the measuring section which can clog or jam; it is accurate and relatively simple, and it is basically an absolute method which permits its use without prior calibration by other means. In hydroelectric turbine testing, a single ultrasonic flow measurement and calculation is made regularly in about 15 minutes, a considerably shorter period than is possible with other test methods. For continuous service, the meter can be made to indicate and record directly in terms of velocity or quantity of flow.

This new bidirectional method measures flow velocity by determining the apparent difference in the velocity of compression waves propagating with and against the flow over a single path.[1] Apparent changes in velocity of propagation are determined by measuring the wave transit times, or differences in transit times, between two fixed points. The new method described in this paper is adaptable to widely varying conditions; however, the equipment, especially the transducers, may have to be designed for the specific application. Knowledge of the method's characteristics and present limitations may even preclude its use where other methods now offer very satisfying solutions.

Because the method is based upon the measurement of fundamental units of time and length, any electronic circuitry which can measure small intervals of time with precision, theoretically can be adapted for use with the method. The bidirectional method, as distinguished from the older upstream-downstream methods, uses but two transducers whose functions as transmitter and receiver are interchangeable. It is even conceivable that the transducers could be both transmitter and receiver simultaneously using differing frequencies or frequency-modulated signals. Or, using electronic gating and pulsing, both transducers could transmit simultaneously, then quickly revert to their receiving function to determine transit times. Another technique, alternate transmissions at a fixed frequency with differences in transit times determined by phase-angle measurement, was used in the initial application.

The validity of the new ultrasonic method was established in the laboratory where errors of 1 per cent and less were obtained with water velocities of 1 to 10 feet per second in a 5-inch by 9-inch steel conduit. These tests of accuracy also showed that the method is affected to only a negligible amount by turbidity, temperature, and departures from uniform velocity distribution normally encountered in straight flow sections. Its practicality was demonstrated by the measurement of the discharge through a hydraulic turbine intake 25 feet high by 16 feet wide. The results of these tests are reported in a previous paper which includes an extensive bibliography.[2] A brief descriptive paper on the flowmeter, under development and test since 1947, was published in 1950.[3]

Principles

The motion or velocity of a fluid is measured with respect to a fixed point or a rigid frame of reference. In the ultrasonic flowmeter a second frame of reference, the fluid itself, must be considered

Paper 55-28, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 15, 1954; made available for printing December 23, 1954.

R. C. Swengel is a consulting engineer in York, Pa., W. B. Hess is with the Safe Harbor Water Power Corporation, Conestoga, Pa., and S. K. Waldorf is with the Pennsylvania Water and Power Company, Lancaster, Pa.

The authors wish to express their sincere appreciation of the assistance received from Robert G. Roush, Research Associate, Institute of Cooperative Research, Johns Hopkins University, in the design of the low output-impedance amplifier and from James M. Barry, System Engineer, Pennsylvania Water and Power Company, in the mathematical development of Appendixes I and II.

Nomenclature

c = velocity of propagation of sound in fluid whose flow velocity is to be measured
c_r = velocity of propagation of sound in transducer rod
d = displacement of transducers along axis of flow and length of measuring section of flowmeter
d' = actual geometric distance between transducers
f = frequency of ultrasonic signals, cycles per second
$j = \sqrt{-1}$ = mathematical complex operator
$n = v/c$
t = difference between upstream and downstream transit times $= t_u - t_d$
t_0 = transit time for a compression wave to travel in either direction from one transducer to other when there is no flow
t_d = transit time for a compression wave to travel downstream from one transducer to other
t_u = transit time for a compression wave to travel upstream from one transducer to other
v = velocity of flow of fluid to be measured
w = width of measuring section of flowmeter
Δ = difference between phase angles measured when transmitting with and against flow
β = angle of path of ultrasonic signal when leaving transmitter, with respect to horizontal reference axis
$\theta = \cos^{-1} c/c_r$ = radiation angle of terminated transducer
ϕ = angle of geometric path between transducer locations, with respect to horizontal reference axis

---

wherein the velocity of propagation is constant. When the fluid moves with respect to the rigid frame of reference, there are apparent changes in propagation velocity within the fluid relative to the rigid frame of reference. The ultrasonic flowmeter utilizes these apparent changes in propagation velocity as a means for determining the velocity of movement or flow.

To measure velocities with the new method, two fixed points on the stationary frame of reference are used. In the most elementary case, the two points are considered on the axis of flow, with a compression wave originating at one of the points and traveling to the other. If there is no flow

$$c = \frac{d}{t_0} \tag{1}$$

When the fluid moves at constant velocity and the wave is transmitted in the direction of flow

$$c + v = \frac{d}{t_d} \tag{2}$$

When the wave is transmitted against the direction of flow

$$c - v = \frac{d}{t_u} \tag{3}$$

Subtracting equation 3 from equation 2

$$(c+v)-(c-v) = \frac{d}{t_d} - \frac{d}{t_u} \tag{4}$$

$$2v = \frac{d}{t_d} - \frac{d}{t_u} \tag{5}$$

or

$$v = \frac{\frac{d}{t_d} - \frac{d}{t_u}}{2} = \frac{d}{2}\left(\frac{1}{t_d} - \frac{1}{t_u}\right) \tag{6}$$

It will be noted that the absolute propagation velocity does not appear in equation 6 for the determination of flow velocity. Fundamentally, therefore, the method can be applied to the measurement of velocity of flow of any fluid, regardless of the absolute propagation velocity which can vary considerably with temperature, pressure, and the medium. It is essential in using equation 6 that absolute elapsed transit times be measured and that they be expressed in absolute units, i.e., seconds.

For the initial development, it appeared more desirable to measure differences in upstream and downstream transit times with sinusoidal signals of a fixed frequency than to use single pulses. A change in the phase angle between the voltages on the transmitting and receiving transducers is a measure of the velocity of flow. This effect is utilized in the new bidirectional method when the measurement is made of the difference in phase angle produced by the alternate upstream and downstream transmissions over a single path. Another basic principle that needs to be considered is the condition where the transmission path is not along the axis of flow but at an angle. This is included in the development of generalized equations given in Appendixes I and II.

It will be noted in equations 30, 32, 35, and 36 in Appendix I that the absolute velocity of propagation in the fluid during measurement must be known when a technique utilizing transit time differences is used. Further, it is interesting and significant to note that the displacement of the transducers along the axis of flow is the dimension of the measuring section entering into the velocity determination. Of course, the width and height of the measuring section must be known to calculate the volume of flow.

Equation 40, in Appendix II, for calculating flow from t_d and t_u with the transmission path at an angle to the axis of flow becomes the same as equation 6 when the path between transducers is along the axis of flow because $\phi = 90$ degrees and $\sin\phi = 1$. In the foregoing analyses, only a uniform constant flow velocity is considered, an ideal not existing in practice. The ultrasonic flow meter is not affected by appreciable departure from uniform velocity distribution, the measuring signals integrating vectorially the velocities through which they pass.

Transducers for Area Measurements

In the preceding section the flow in a single plane is analyzed. In practice, it is usually desirable to measure a volume of flow which involves the determination of the average flow velocity over a cross section. To accomplish this, linear transducers were developed for use in rectangular ducts which in effect are line sources of ultrasonic radiation rather than point sources. When two such transducers are properly positioned, the received signal will have traversed all elements of the flow cross section and will have been affected by all components of the flow velocity. In the initial application of the flowmeter, which was the measurement of the discharge through one of the three bays comprising the intake of a 42,500-horsepower low-head hydroelectric turbine, velocities were averaged over a cross section of 400 square feet for flows up to 2,500 cubic feet per second.

Fig. 1 shows this installation and may convey some impression of the large quantities of water measured. These transducers were found to be in excellent condition after being totally submerged for 1 year.

A linear transducer consists of three principal parts—the driver, the mechanical transformer or horn, and the antenna or radiator. Depending upon the frequency used, the driver may be piezoelectric for the higher frequencies or magnetostrictive for the lower frequencies The horn is a mechanical coupling or impedance-matching device between the driver and the antenna.[4] It has an exponential taper and its size is dependent upon the frequency at which it is used. The stainless steel antenna rod shown in Fig. 1 has a diameter of 1/4 inch.

Transducers may be either resonant or nonresonant, the latter being the more desirable because of their highly directional characteristics which help to eliminate the effects of echoes and other undesired transmission paths. Radiation patterns can be predicted within narrow limits from the relations between propagation velocities in the antenna and the fluid medium. As a nonresonant system, the undriven end of the transducer rod is made to absorb any acoustic energy not radiated into the fluid. This produces a radiation pattern having the form of a cone, as represented in Fig. 2. In water, c is about 4,800 feet per second, and c_r is about 17,000 feet per second in chrome stainless steel.

Appendix III gives a method for calculating the proper tilt angle when mounting nonresonant transducers. It will be noticed in Fig. 6 that, in addition to the transducers being placed on opposite walls, their driven ends are placed facing in opposite directions. This is done to have the path of every element of the ultrasonic signal pass through the same length of transducer rods and undergo the same phase shift and attenuation due to the rods. This ensures that differences in the signal components are caused by fluid velocity effects only.

Electronic Equipment

Fig. 3 is a block diagram of the equipment used for proving the validity of the method and for hydroelectric turbine testing. It utilizes continuous transmission at a fixed frequency with cyclic reversal of the direction of transmission and measurements of the phase angle between transmitted and received signals. The difference between the phase angles for upstream and downstream transmissions is the measure of flow velocity. This technique was used for testing because it appeared to be the least complicated for applications with water subject to very slow temperature changes.

The measuring system has three principal functions—transmitting, interchange of transducers, and measurement of phase angle. The power source has three features:

1. The frequency is adjustable over a range of 5 per cent and has very high stability.
2. Changes in load do not affect the oscillator frequency.
3. The reference voltage derived from the power source is not affected by any difference in impedances of the two transducers.

The oscillator chosen for the power supply is a *6AG7* in a modified Clapp circuit; see Fig. 4. A voltage having high harmonic content is taken from the plate circuit of the *6AG7* for direct comparison with the standard frequency broadcast of the National Bureau of Standards station *WWV*. The Clapp circuit offers the advantage of high stability and permits close adjustment of the operating frequency. The buffer, a *6SK7* tuned

Fig. 4. 25-kc power supply

amplifier with a *6J5* cathode follower, eliminates the effects of load changes on the oscillator frequency.

The output amplifier comprising the balance of the circuit has an output impedance of a fraction of 1 ohm and supplies a few watts with adequate current for the highly capacitive load of a crystal transducer. An inductance is placed in series with the transmitting transducer to lower the load impedance and to obtain a better match between the amplifier and transducer. The reference voltage, Fig. 4, is taken directly from the output terminals of the output amplifier to eliminate any possibility of phase shifts within the amplifier which might occur as the result of differing transducer load impedances.

The receiving amplifier in Fig. 3 is conventional except that precautions were taken to avoid phase shifts with changes in amplitude of the received signal. This condition is readily obtained by the use of air-core inductors. The mixer circuit is also conventional, using a heterodyne oscillator to reduce the frequency of the two incoming signals to approximately 500 cycles per second. This is done to make the rise time of the square-wave pulses actuating the phase-angle circuit a negligible fraction of 1 cycle.

The phase-angle recorder circuit is similar to several commercially available types using clipping and squaring of the two sine wave voltages along with an Eccles-Jordan switching circuit to produce a pulsating direct voltage whose average value is directly proportional to the phase angle between the two voltages being compared. This voltage is recorded on a Minneapolis-Honeywell 10-inch high-speed electronic strip chart recorder calibrated in degrees of phase angle. This recorder has a very linear response which is important for the accurate determination of phase-angle differences. A phase shifter inserted in either channel is convenient for phase-angle calibration as well as for positioning the record on the chart.

The coaxial mechanical interchanging switch was designed expressly for this application. The most important feature of its design is the high degree of isolation between transmitting and receiving circuits attained by the use of thorough shielding. All contacts are of the silver wiping type to minimize any change in impedance of the coaxial cables with which it is used. A Geneva gear train on a slow-speed gear motor provides the necessary torque with the required dwells and time intervals for switching. The switching cycle for this application is 10 seconds.

Practical Considerations

With any method of measurement, certain precautions must be taken to attain a high degree of accuracy. The necessary precautions and considerations for the attainment of a high degree of accuracy with the ultrasonic flowmeter are as follows:

1. There must be accurate knowledge of the velocity of propagation of sound in the fluid to be measured when a phase-angle or other transit-time difference measuring technique is used. For water, accurate data are available.[8]
2. The approximate range of flow velocity to be measured.
3. The limiting physical dimensions of the measuring section must be known.
4. Transducers must be chosen or designed to have radiation patterns suitable for the measurement to be made.
5. No mechanical nor electric coupling between the transmitting and receiving circuits is permissible other than the acoustic path through the fluid being measured. Also, there must be no coupling between the receiving and reference voltage circuits prior to phase-angle comparison.
6. There must not be undesired acoustic echo paths in the measuring section. This is obtained when there is a linear relation between phase angle and frequency for transmissions in the measuring section in the range of frequency used for measurement.
7. Transducer radiation patterns must not be modified by the transducer mounting.
8. Equipment must be independent of surroundings and of variations in supply voltage as well as free from phase shifts arising from changes in signal levels.

Conclusions

1. The bidirectional ultrasonic method makes possible the determination of flow velocity of a fluid with accuracy even when the physical properties of the fluid are known only approximately.
2. Because the method is based on measurements of fundamental units of time and length, it requires no velocity calibration by other means or methods prior to use and is amenable to rigorous mathematical analysis.
3. The method is quite versatile because signal transit times can be measured in several ways, the transducers can have many forms, and the electronic circuitry can be varied to satisfy the designer's needs and judgment.
4. Usually the transducers can be installed without alteration of the flow section and without interference to flow.
5. The velocity-sensitive elements, having no moving parts nor openings, are practically immune to clogging and jamming.
6. A new class of transducers, the linear or antenna type, has been developed and applied. This principle of utilizing ultrasonic driving elements on radiating systems makes possible ultrasonic analogues of electromagnetic antennas and radiation patterns.
7. Extensive laboratory tests with a rectangular 5-inch by 9-inch duct prove the method's practicality and ability to measure accurately over appreciable ranges of temperature, turbidity, turbulence, and flow distortion.
8. The ultrasonic method is especially well suited to the measurement of large volumes of flow, as shown by its application to the measurement of the discharge of a 42,500-horsepower hydroelectric turbine.

Appendix I. Derivation of Velocity Equations in Terms of Transit Time Differences

The conditions shown in Fig. 5 represent flow at constant and uniform velocity $\mathbf{v}$ in a measuring section of length d and width w. In Fig. 5(A), where the direction of transmission of the ultrasonic signal is upstream, the geometric path AB between transducer locations A and B makes the angle ϕ with the horizontal reference axis. In Fig. 5(B), where the ultrasonic signal is transmitted in the opposite direction, BA makes the angle 180 degrees $+\phi$ with the reference axis.

When there is no flow, the ultrasonic signal follows the identical paths AB or BA, depending upon the direction of transmission

$$AB = BA = d' = \frac{d}{\sin\phi} = ct_0 \tag{7}$$

When there is flow at velocity $\mathbf{v}$, the vector relationship in Fig. 5(A) in polar form is

$$ct_u\underline{/\beta} + \mathbf{v}t_u\underline{/270^\circ} = d'\underline{/\phi} \tag{8}$$

For the ultrasonic signal to reach point B when there is flow, it must leave the transmitter at angle β instead of at angle ϕ.

Dividing equation 8 by t_u,

$$c\underline{/\beta} + \mathbf{v}\underline{/270^\circ} = \frac{d'}{t_u}\underline{/\phi} \tag{9}$$

Rewriting 9 in rectangular form and placing $j\mathbf{v}\sin 270$ degrees $= -j\mathbf{v}$

$$c\cos\beta + jc\sin\beta - j\mathbf{v} = \frac{d'}{t_u}\cos\phi + j\frac{d'}{t_u}\sin\phi \tag{10}$$

Separately equating reals and imaginaries in equation 10

$$c\cos\beta = \frac{d'}{t_u}\cos\phi \tag{11}$$

$$c\sin\beta - \mathbf{v} = \frac{d'}{t_u}\sin\phi \tag{12}$$

$$\cos\beta = \frac{d'}{ct_u}\cos\phi \tag{13}$$

$$\sin\beta = \frac{d'}{ct_u}\sin\phi + \frac{\mathbf{v}}{c} \tag{14}$$

Squaring equations 13 and 14, adding

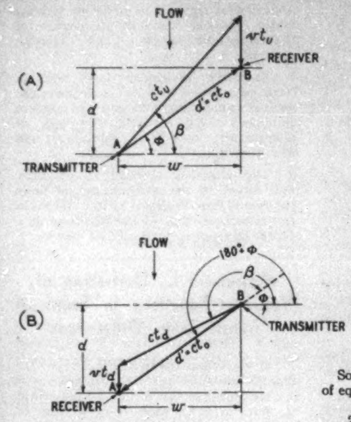

Fig. 5 (left). Vector relationships

A—upstream transmission
B—downstream transmission

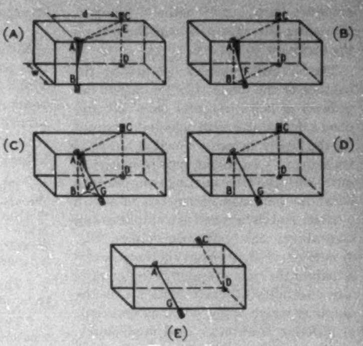

Fig. 6 (right). Determination of tilt angle for terminated transducers

them, and replacing $\sin^2\beta+\cos^2\beta$ by its equivalent, unity

$$1=\left(\frac{d'}{ct_u}\right)^2\sin^2\phi+2\frac{d'\mathbf{v}}{c^2t_u}\sin\phi+\frac{\mathbf{v}^2}{c^2}+\left(\frac{d'}{ct_u}\right)^2\cos^2\phi \quad (15)$$

Combining the first and fourth terms on the right-hand side of equation 15, replacing $\sin^2\phi+\cos^2\phi$ by its equivalent, unity, multiplying through by c^2, and rearranging terms

$$\mathbf{v}^2+\frac{2d'\mathbf{v}}{t_u}\sin\phi+\left(\frac{d'}{t_u}\right)^2=c^2 \quad (16)$$

For ultrasonic signal transmission downstream, as represented in Fig. 5(B), equation 17 can be derived by the method followed to obtain equation 16

$$\mathbf{v}^2-\frac{2d'\mathbf{v}}{t_d}\sin\phi+\left(\frac{d'}{t_d}\right)^2=c^2 \quad (17)$$

For convenience in computation and as a criterion of applicability for the several forms of equations for flow velocity, the ratio n is introduced

$$n=\mathbf{v}/c \quad (18)$$

$$\mathbf{v}=nc \quad (19)$$

In equation 16 substitute equation 19 for $\mathbf{v}$ and equation 7 for d'

$$n^2c^2+\frac{2(ct_0)(nc)}{t_u}\sin\phi+\frac{c^2t_0^2}{t_u^2}=c^2 \quad (20)$$

Multiplying equation 20 through by t_u^2/c^2

$$n^2t_u^2+2nt_0t_u\sin\phi+t_0^2=t_u^2 \quad (21)$$

$$(1-n^2)t_u^2-(2nt_0\sin\phi)t_u-t_0^2=0 \quad (22)$$

Equation 22 is a quadratic of the form

$$ax^2+bx+c=0 \quad (23)$$

The standard solution to equation 23 is

$$x=\frac{-b\pm\sqrt{b^2-4ac}}{2a} \quad (24)$$

Solving equation 22 for t_u, using solution of equation 24

$$t_u=\frac{2nt_0\sin\phi\pm\sqrt{(2nt_0\sin\phi)^2+4(1-n^2)t_0^2}}{2(1-n^2)}$$

$$=t_0\left(\frac{n}{1-n^2}\right)\sin\phi\pm\frac{\sqrt{(2nt_0\sin\phi)^2+4(1-n^2)t_0^2}}{2(1-n^2)} \quad (25)$$

The analogous equation for t_d can be derived from equation 17 by similar procedure and is identical to equation 25 except that $\sin\phi$ has a negative sign. The first term, therefore, has a negative sign in the equation for t_d, but the second terms are identical in equations for both t_u and t_d because $\sin\phi$ is squared. Therefore

$$t=t_u-t_d=2t_0\left(\frac{n}{1-n^2}\right)\sin\phi \quad (26)$$

or

$$tn^2+(2t_0\sin\phi)n-t=0 \quad (27)$$

Solving for n using standard quadratic solution of equation 24

$$n=\frac{-2t_0\sin\phi\pm\sqrt{4t_0^2\sin^2\phi+4t^2}}{2t} \quad (28)$$

Solving equation 28 for $\mathbf{v}$ after substituting $n=\mathbf{v}/c$ from equation 18 and $t_0=d/(c\sin\phi)$ from equation 7

$$\mathbf{v}=\frac{-d\pm\sqrt{d^2+c^2t^2}}{t} \quad (29)$$

Since $\mathbf{v}$ is always positive or zero, equation 29 becomes

$$\mathbf{v}=\frac{\sqrt{d^2+c^2t^2}-d}{t} \quad (30)$$

If sinusoidal signals of frequency f are used to measure t by determining the phase-angle difference Δ between the upstream and downstream transmission conditions

$$t=\frac{\Delta°}{360°}\times\frac{1}{f}=\frac{\Delta}{360f} \quad (31)$$

Substituting equation 31 in equation 30

$$\mathbf{v}=\frac{\sqrt{d^2+(c^2\Delta^2)/(360f)^2}-d}{\Delta/360f}$$

$$=\frac{\sqrt{(360fd)^2+c^2\Delta^2}-360fd}{\Delta} \quad (32)$$

Equations 30 and 32 can be replaced by simpler equations if the ratio $n=\mathbf{v}/c$ is small. In the measurement of the discharge of hydraulic turbines, $n\approx 10/4{,}800$ and $n/(1-n^2)\approx n$ to within one part in 230,400. Under such circumstances, equation 26 can be simplified to

$$t=2t_0n\sin\phi=2t_0(\mathbf{v}/c)\sin\phi \quad (33)$$

from which

$$\mathbf{v}=\frac{ct}{2t_0\sin\phi} \quad (34)$$

Since $t_0=d/(c\sin\phi)$ from equation 7

$$\mathbf{v}=(c^2t)/2d \quad (35)$$

To convert equation 35 for use where Δ is measured, substitute equation 31 in equation 35

$$\mathbf{v}=(c^2\Delta)/(720fd) \quad (36)$$

Appendix II. Derivation of General Velocity Equation in Terms of Absolute Transit Times

Subtracting equation 17 from equation 16 eliminates c

$$(2d'\mathbf{v}\sin\phi)/t_u+(2d'\mathbf{v}\sin\phi)/t_d+(d'/t_u)^2-(d'/t_d)^2=0 \quad (37)$$

Combining terms and dividing by d'

$$2\mathbf{v}\sin\phi\left(\frac{1}{t_u}+\frac{1}{t_d}\right)=d'\left(\frac{1}{t_d^2}-\frac{1}{t_u^2}\right)$$

$$=d'\left(\frac{1}{t_d}-\frac{1}{t_u}\right)\left(\frac{1}{t_d}+\frac{1}{t_u}\right) \quad (38)$$

which results in

$$\mathbf{v}=\frac{d'}{2\sin\phi}\left(\frac{1}{t_d}-\frac{1}{t_u}\right) \quad (39)$$

Substituting for d' from equation 7

$$v=\frac{d}{2\sin^2\phi}\left(\frac{1}{t_d}-\frac{1}{t_u}\right) \qquad (40)$$

This general equation becomes equation 6 when $d'=d$, because ϕ is then 90 degrees and $\sin\phi=1$.

Appendix III. Calculation of Transducer Tilt Angle

Fig. 6 shows graphically a method for determining the proper tilt angle for mounting terminated transducers in a rectangular flow section. In Fig. 6(A), both transducers are shown in a vertical position displaced along the axis of flow by a distance d. The angle CAE is 90 degrees$-\theta$, where θ is the radiation angle in Fig. 2. If the transducers were mounted vertically as illustrated, the section of flow included in triangle ACE would not be included in the velocity measuring area.

As a first step, the transmitting transducer is moved to position AF, sufficiently to make E coincide with C, where F is on the line BD. The shortcoming of this position is the omission from measurement of the flow in triangle ABF. Angle $BAF=$ 90 degrees$-\theta$. Therefore, BF can be determined from the relation $BF=AB\times\tan$ (90 degrees$-\theta$).

In Fig. 6(C), the transmitting transducer has been rotated about axis AC until the transducer coincides with the wall, assuming its final position AG. Since BFG is a right angle because of this rotation about AC and angle $GBF=\tan^{-1} w/d$ is fixed by the dimensions of the duct, BG can be determined from the equation $BG=BF/(\cos GBF)$.

In Fig. 6(D), it can be seen that the tilt angle BAG is $\tan^{-1}(BG)/(AB)$. In Fig. 6(E), the receiving transducer CD has been placed in its final position by making it parallel to transducer AG by rotation in the plane of the wall about point C.

◆

Discussion

Fred E. Cornwell (Bureau of Reclamation, Denver, Colo.): This paper deals with a subject of vital importance to the engineer who is associated with hydroelectric installations. There is no question but that an accurate, dependable method of making flow measurements on large installations presents many problems which have not been solved satisfactorily. A method which can give results of a flow measurement in a time approaching 15 minutes would appear to offer real advantages, provided it can yield accurate, dependable results under field conditions. The authors present a very interesting approach with their ultrasonic meter.

It is difficult to evaluate the general procedure and accuracy of the instrument without further technical details and possibly test data. The authors state, "The ultrasonic flowmeter is not affected by appreciable departure from uniform velocity distribution, the measuring signals integrating vectorially the velocities through which they pass." How could variable cross-sectional areas associated with these variable velocities be integrated to give appropriate flows? The question of nonuniform velocities has been at the root of many difficulties encountered with other methods. It is stated that the instrument requires no prior calibration in that it is basically an absolute method It appears to me that some calibration, possibly as a function of conduit shape and average velocity, would be essential.

In the paper reference is made only to rectangular shapes. For anything approaching general usage, applicability to circular shapes would be highly desirable. Any work related to this question would be of interest. Test data on the discharge measurements for the 42,500 -horsepower hydroelectric turbine on which this instrument was used would be of assistance in evaluating the device. If available, similar data by alternate methods should be included.

The ultrasonic flowmeter, or future modifications of it, may be found of use by the hydraulic industry. However, before it can gain general acceptance, the hydraulic engineer will need to be convinced that it does consider realistically the difficulties which have confronted him in the past I hope that my questions will assist in clarifying some of the points involved.

J. R. Leslie (Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): The authors are to be commended for originating and aptly describing a new technique in the hydraulic measurement field. The scheme described appears to have great promise. Could the authors answer one or two questions concerning the case of nonuniform flow? As is well known, some of the difficulties with present techniques are caused by the presence of a nonuniform distribution of velocity across the intake, owing to either turbulence or the changing cross section. Is it possible then, on theoretical grounds, to show that the method of measurement yields a true average of the velocity? Secondly, the presence of turbulence in the water should affect the amplitude of the received signal, and possibly make the instrument nonworkable. Have any measurements of signal attenuation across the channel been made?

Robert T. Knapp (California Institute of Technology, Pasadena, Calif.): The accurate measurement of the flow rate of large quantities of liquid has been serious problem for a great many years. Most of the methods of measurement found satisfactory for small flow rates are not applicable to the larger flows, principally because they are not primary measurements but require calibration, and the calibration is not possible with large flow rates because of the tremendous construction cost of suitable calibrating basins or weighing tanks. Therefore, the presentation of a new primary method of flow measurement is always of great interest to the engineering profession. This paper appears to be of particular importance because it not only proposes a new primary method of flow measurement, i.e., one which does not require calibration but also a method which does not require unduly expensive equipment or serious modification of the flow channel. Furthermore, although it basically measures the instantaneous flow rate, the measurements can be repeated so rapidly as to form a continuous record of flow rate, thus making it adaptable to unsteady as well as to steady flow.

The paper deals primarily with the general principles of the method and two quite different methods of use, one requiring prior knowledge of the velocity of sound in the flowing liquid, and the other independent of it. However, very little has been said concerning the inherent limitations of the method. Additional discussions of the following points would be valuable: Factors affecting upper limits of accuracy attainable, either in the instrumentation or caused by the flowing fluid; effect of variation in velocity across the cross section, particularly in the direction perpendicular to the direction of travel of the measuring sound waves; and methods of application to nonrectangular cross sections, in particular to circular ones.

The authors are to be congratulated upon the presentation of this paper. It is hoped that they will be encouraged to pursue vigorously the development of this new flow meter.

F. L. Lawton (Aluminum Laboratories Limited, Montreal, Que. Canada): The authors have succeeded in developing a method of measurement of fluid flows which is apparently adaptable to economic permanent installation so that the efficiency of a number of water wheels in a plant can be expeditiously determined from time to time. The authors could confirm this?

It is well known that the efficiency of water wheel runners varies over a long period of time owing to changes in the profile of the blades arising from repairs associated with pitting from cavitation. Such repairs restore the exact profile. Consequently, the efficiency of the unit varies. This becomes of importance in achieving optimum economy of water usage and maximum kilowatt-hour generation from a group of units.

It would be interesting to have the authors' opinion on the relative accuracy of the ultrasonic method as applied to the measurement of flow through relatively long penstocks as contrasted with other methods such as the salt-velocity and Gibson methods.

C. W. Watchorn (Pennsylvania Water and Power Company, Baltimore, Md.): The real significance of the paper is that a very accurate method for measuring the performance of hydro units under difficult conditions that might not be obtained satisfactorily otherwise is reported, since such information is the basis for the potential improvement in and maintenance of system operating economies that can amount to very large savings under various conditions, particularly in combined hydro and steam systems.

These savings could stem from several sources, e.g.: the knowledge as to the correct characteristics of the units provides a basis for their economical loading both as individual units and also as among the several units in a plant; the method provides a means for readily checking unit performance as a basis for possible adjustment or repairs in case there are indications of sufficient deviation from expected performance to justify such measures; and such knowledge provides the basis for the economical co-ordination of hydro and steam generation.[1]

REFERENCES

1. CO-ORDINATION OF HYDRO AND STEAM GENERATION, C. W. Watchorn. *AIEE Transactions*, vol. 74, pt. III, Apr. 1955, pp. 142–50.

R. C. Swengel, W. B. Hess, and S. K. Waldorf: Several questions of Mr. Cornwell, Mr. Leslie, and Mr. Knapp are answered in reference 2. Perpahs it will add to the scope of this paper to restate that laboratory tests on nonuniform flow of somewhat greater magnitude than expected in the turbine intake indicated no errors when the asymmetry was parallel to the plane of the transducers. Deviations of 2 per cent were found when the asymmetry was perpendicular to the plane of the transducers. The latter can be corrected by utilizing four transducers in place of the usual two. Turbulence created in the laboratory tests by various numbers and widths of steel bars in the flow stream immediately ahead of the measuring section produced no measurable errors. The turbulence did attenuate the signal slightly but not enough to warrant measurements; it is estimated that it was of the order of 5 to 10 per cent.

We realize that the method has a wider field of application to circular flow sections; however, our work was confined to rectangular sections because of the specific problem to be solved. Mathematical analysis and some experiments indicate that the method is applicable to other geometric sections; however, the precision of such measurements has not been determined. Physical problems in sound propagation and transducer design will probably vary with each conduit shape and will require additional research and development.

The ultimate accuracy of the method depends primarily upon a thorough knowledge of the sound-propagation path between transducers. Proportional changes in phase angle or transit time corresponding to changes in frequency of the sound waves for a no-flow or a stable-flow condition is one method of obtaining such knowledge. Instrumentation is secondary and depends upon the degree of reliability and accuracy desired.

Regarding Mr. Lawton's statement, there is no reason why an installation could not be made permanent and periodic efficiency tests conducted. Furthermore, we believe that with additional development of the instrumentation the measurements could be made continuous. The development of the ultrasonic method in this particular case was for turbine intakes too short for either the salt-velocity or Gibson methods. It is our opinion that comparable accuracies could be obtained on rectangular sections suitable to the three methods of measurement.

In view of Mr. Watchorn's and Mr. Lawton's experience and close association with the economic phases of power generation, their comments concerning the importance of obtaining actual performance characteristics of hydraulic turbines are greatly appreciated.

Magnetization of Transformer Cores During Impulse Testing

L. C. LEONI
ASSOCIATE MEMBER AIEE

THE American Standards Test Code[1] states, in paragraph 22.121, that "Because of the nature of impulse test failures, one of the most important matters is the detection of failure." It suggests a number of indications of insulation failure such as noise within the transformer and the presence of smoke or bubbles. Another means suggested for detecting insulation failure is to compare oscillographic records of the applied voltage and neutral current waves taken during reduced and full-wave tests. Any deviation between the applied voltage wave shapes or between neutral current wave shapes obtained during the reduced full-wave or full-wave tests "indicates changes in impedance arising from insulation breakdown within the transformer, or changes in the impulse circuit external to the transformer, and the cause should be investigated."[1] Under this interpretation, if the impulse circuit external to the transformer is judged satisfactory, the transformer insulation must be considered as having failed to pass the test.

A 250-kva 2,400/4,160Y single-phase transformer was recently tested according to this accepted technique, and was reported to have failed on the basis of increases noted in the oscillograms of neutral current, as well as increased sound in the unit on repeated impulses. The oscillograms indicated that several consecutive applications of the reduced full waves produced successively increasing neutral currents. This effect had been observed by one of the authors in development tests dating back to 1945, and it led to an investigation of possible causes for nonlinear responses of this type. This paper satisfactorily explains these effects by considering the accumulation of residual magnetization which is produced when unidirectional impulse are applied.

This experience demonstrates very clearly that unless the phenomenon is recognized, any difference between the wave shapes during the reduced full-wave and full-wave tests may be falsely interpreted as indication of failure of the transformer insulation.

It is the purpose of this paper to discuss these effects more thoroughly and to establish criteria by which magnetization during impulse testing may be anticipated. Suggestions are also offered for procedures which may permit a better comparison of the waves at reduced and full-wave levels and which minimize the accumulation of residual flux.

The relative effects on the applied voltage wave and the neutral current wave with a 1-turn short circuit will be shown

Paper 55-30, recommended by the AIEE Transformers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 16, 1954.

The authors wish to thank members of the General Electric High Voltage Laboratory, particularly J. H. Hagenguth, A. F. Rohlfs, P. L. Waldon, and A. J. Welling, for their invaluable help in the experimental stages of these tests.

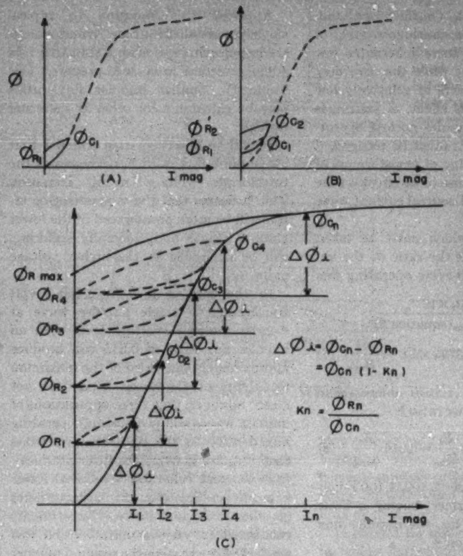

Fig. 1 (left). Sketch of magnetization curve showing cumulative effects of successive impulse waves on winding with initially demagnetized core

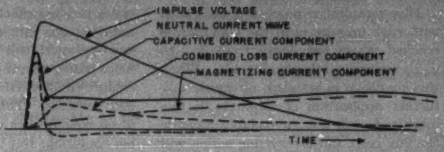

Fig. 2 (above). Typical voltage and neutral current wave shapes

to be much larger than the core magnetization effects.

Mechanics of Core Magnetization

Because impulse test waves are prescribed in transformer standards in terms of times to crest and half value, it is most practical to show the relation between volt-time integrals and core magnetization.

The degree to which transformer cores are magnetized by unidirectional voltages depends upon the voltage, wave shape, number of impulses, and the magnetic characteristics of the core. The flux produced by a single impulse depends upon the time integral of the impulse voltage wave in accordance with the general law of induction

$$e = -N\frac{d\phi}{dt}10^{-8}$$

$$\phi = \frac{-10^8}{N}\int_0^t e\,dt \qquad (1)$$

where

ϕ = total lines of flux, maxwells
e = volts
N = total active turns
t = time, seconds

The flux produced by one impulse, which will be represented by $\Delta\phi_i$, is usually considerably less extensive than the normal 60-cycle operating flux. For 60-cycle operation the flux is

$$\phi_{60} = \frac{10^8}{N}\int_0^{1/240} 1.414E_{\text{rms}} \sin \omega t\,dt$$

$$= 375{,}000\frac{E_{\text{rms}}}{N} \text{ lines of flux} \qquad (2)$$

For an impulse wave excitation, using some relatively simple approximations for the time integral of a standard type of impulse derived in the Appendix

$$\Delta\phi_i = \frac{10^8}{N}\int_0^t e\,dt = 140\frac{E_i t_i}{N} \text{ lines of flux} \qquad (3)$$

where

E_i = impulse crest, volts
t_i = time in microseconds to half crest value according to standard definitions

To illustrate the impulse magnetization process, refer to the typical magnetization curves in Fig. 1, which start from a completely demagnetized core condition.

In Fig. 1(A) ϕ_{C1} indicates the maximum flux attained by one impulse wave of such voltage as to produce a flux increment of $\Delta\phi_i$. When the impulse is over, the flux does not necessarily return to zero because of the retentivity characteristics of the magnetic circuit. Instead, the flux will decay to some point ϕ_{R1} which is the residual flux in the core after one impulse.

When a succeeding impulse wave of the same amplitude and shape is applied, the flux increment $\Delta\phi_i$ is added to the residual flux ϕ_{R1} to reach a new flux crest of $\phi_{R1} + \Delta\phi_i = \phi_{C2}$ as shown in Fig. 1(B). The flux then decays to a new residual value ϕ_{R2}. This is essentially a d-c magnetization process.

The degree to which the flux crest will build up with successive applications of the impulse wave depends on the retentivity characteristics of the particular core. If the core has no retentivity characteristics, the flux in the core would decay to zero after each impulse. Therefore, the ratio ϕ_{R1}/ϕ_{C1} would be zero and no build-up in core magnetization would result with successive impulse waves. However, if the core has retentivity characteristics it retains some of the flux from the preceding impulse wave, therefore a build-up in core magnetization is likely. If $\phi_{R1}/\phi_{C1} = k_1$, $\phi_{R2}/\phi_{C2} = k_2$, etc., and $\phi_{Rn}/\phi_{Cn} = k_n$, where n is the number of impulse waves of a given wave shape and amplitude applied, the build-up in flux crest will proceed in a step-by-step manner as shown in Fig. 1(C). This process can be expressed by the equations

$$\begin{aligned}
\phi_{C1} &= \Delta\phi_i\\
\phi_{C2} &= k_1\phi_{C1} + \Delta\phi_i = k_1\Delta\phi_i + \Delta\phi_i = \Delta\phi_i(k_1+1)\\
\phi_{C3} &= k_2\phi_{C2} + \Delta\phi_i = \Delta\phi_i(k_1+1)k_2 + \Delta\phi_i\\
&= \Delta\phi_i(k_1k_2 + k_2 + 1)\\
\phi_{C4} &= k_3\phi_{C3} + \Delta\phi_i\\
&= \Delta\phi_i(k_1k_2k_3 + k_2k_3 + k_3 + 1) \qquad (4)
\end{aligned}$$

Following this procedure, the flux crest resulting from n successive applications of the impulse wave may be approximated to a satisfactory degree.

If k is approximately constant for the region of the magnetization curve under consideration, the equation for flux crest reduces to

$$\phi_{Cn} = \Delta\phi_i(1 + k + k^2 \ldots + k^{(n-1)})$$

$$= \Delta\phi_i\frac{1-k^n}{1-k} \qquad (5)$$

Table I. Impulse Flux Ratios

Voltage Rating, E_{rms}	BIL E_i, Kv	Ratio, E_i/E_{rms}	Impulse Flux Ratio, F_i
2,400/4,160Y	60	25	0.375
7,200/12,470Y	95	13.2	0.198
14,400	95	6.6	0.099
69,000	350	5.07	0.076

This cumulative process is continued with each impulse until the condition is reached where the decay from ϕ_{Cn} to ϕ_{Rn} is approximately equal to $\Delta\phi_i$. When this condition is satisfied, obviously any further application of impulses of this magnitude will not appreciably increase the flux crest and a recycling action will occur on a minor loop which has a vertical component of $\Delta\phi_i$ and a "bias" or residual flux of ϕ_{Rn}.

Theoretically, an infinite number of impulses would be required to reach a recycling point anywhere below the "knee" of the normal magnetization curve. However, a more realistic approach is to assume that, for all practical purposes, recycling occurs when

$$\phi_{Cn}-\phi_{Rn}=0.95\Delta\phi_i \qquad (6)$$

To determine whether or not a certain transformer will exhibit this residual build-up during impulse testing and if so to what extent, it is necessary to have a magnetization curve and a hysteresis loop diagram of the type of core used in the transformer. As an example in extremes, assume a core with several joints and air gaps. Such a core will have inherently high magnetizing current but the core can be excited to a relatively high flux density without exhibiting any appreciable residual effect. On the other hand, a core made with a continuous strip of low loss steel will have inherently low magnetizing current while the core may exhibit residual effects at relatively low flux densities. This effect, of course, is of no consequence under normal operating conditions but it must be recognized during impulse testing of transformers of certain ratings because of its effect on the impulse voltage and neutral current wave shapes.

Another factor which must be taken into consideration is the ratio of the impulse flux to the 60-cycle operating flux

$$F_i=\frac{\Delta\phi_i}{\Delta\phi_{60}}=\frac{1.4E_it_i\times10^{-6}}{0.00375E_{rms}(\text{equation 2})}$$

$$=373t_i\times10^{-6}\times\frac{E_i}{E_{rms}} \qquad (7)$$

For a standard 1.5x40 microsecond wave, the impulse flux ratio is

$$F_i=373\times40\times10^{-6}\times\frac{E_i}{E_{rms}}=0.015\frac{E_i}{E_{rms}} \qquad (8)$$

For a single-phase 2,400/4,160 *Y*-volt distribution transformer, having a basic impulse level of 60 kv, the impulse flux ratio is, from equation 8

$$F_i=0.015\times\frac{60{,}000}{2{,}400}=0.375$$

Applying this equation to typical single-phase distribution transformers, the impulse flux ratios for a standard 1.5x 40-microsecond wave was prepared (see Table I). Similar impulse flux ratios may be calculated for other transformer ratings.

It will be observed from Table I that the impulse flux ratio F_i decreases as the transformer voltage rating increases. This indicates that the magnetization effect will be more pronounced in the lower voltage ratings and, generally speaking, will be negligible in the higher voltage units.

In the case of a 2,400/4,160 *Y*-volt transformer, a single impulse wave at standard impulse voltage level with an impulse flux ratio of 0.375 will produce approximately one-third of the maximum rated flux of the core. This does not mean, however, that three applications of impulse waves will produce full operating flux density in the core because, when each impulse is over, the flux will decay from its crest value to a somewhat lower value, depending upon the characteristics of the particular core. Experiments conducted on various units verified this method of calculating the residual magnetization.

cerned only with the flux produced by the voltage-time area of an impulse voltage wave and the degree of residual flux remaining after the impulse is over. To produce a certain amount of flux, a magnetizing current must flow through the windings. The value of magnetizing current required to produce a given value of flux is determined from the magnetization curve similar to that shown in Fig. 1(C).

When using the neutral-current method of fault detection during impulse testing, this magnetizing current must flow through the neutral impedance circuit; therefore, any changes in the flux crest during impulse testing will be reflected in changes in the neutral-current wave shape. When successive impulses increase the flux crest to levels above the knee of the magnetization curve, the magnetizing current may increase to values many times that of the normal exciting current, Fig. 1(C). If the loading of the impulse circuit depends primarily upon the unit being tested rather than external circuit parameters, then the voltage wave may be considerably affected.

The neutral current wave contains not only the magnetizing current component but also the capacitive current and loss current components as illustrated in Fig. 2. The capacitive current is the charging current which flows through the capacitance of the windings and is of relatively short duration. The magnetizing current component continues to increase as long as a voltage exists across the winding. It follows that the maximum magnetizing current occurs when the excitation voltage approaches zero. At this time the capacitance and loss current components will have decayed to a negligible value; therefore, the neutral current consists primarily of the magnetizing current when the impulse voltage is at or near zero.

It should be quite apparent from the foregoing that changes in the neutral current and applied wave shape may definitely be attributed to changes in core magnetization during impulse tests on certain transformer ratings, and this effect should not be misconstrued as indicative of insulation failure. It should also be stated that, since an appreciable amount of flux may be produced during each impulse, it is reasonable to assume that some degree of magnetostriction occurs which will produce an impact sound.

Experimental Studies in Core Magnetization by Impulse Voltage

To demonstrate the effect of residual magnetization on the impulse voltage and neutral current wave shapes, a series of tests was staged on the 250-kva 2,400/4,160*Y*-volt single-phase transformer referred to at the start of this paper. The basic impulse level of the primary winding was 60 kv.

Tests were started with the core completely demagnetized by slowly decreasing a 60-cycle excitation voltage to zero prior to each set of tests. Then the impulse voltage was applied to one end of the winding while the other end was grounded through a resistance shunt, paralleled by a capacitor to by-pass some of the capacitive charging current. Simultaneous oscillograms of voltage and neutral current waves were recorded.

The first series of impulse tests consisted of several applications of waves at 50-per-cent (%) basic impulse insulation level (BIL), 30-kv. Tracing of the applied voltage and neutral current waves are shown in Figs. 3(A) and 3(B) respectively.

It will be observed that recycling occurred at about the sixth impulse where the neutral current stopped increasing on successive waves. Recycling in this case occurred at a region on the magnetization curve considerably below the saturation level as indicated by the neutral current, which at the time near voltage zero (about 280 microseconds) was less than the normal magnetizing current crest.

In the next series of tests, several impulse waves at 100% BIL (60 kv) were applied, again starting from zero magnetization. Tracings of the applied voltage and neutral current waves are shown in Figs. 4(A) and 4(B) respectively. It is evident from the neutral current waves that recycling occurred at about the sixth application since the neutral current no longer increased on successive waves. Here recycling occurred above the knee of the magnetization curve because the $\Delta\phi_1$ supplied by the impulse voltage exceeded the difference between flux crest and residual-flux at the knee of the normal curve. When this condition exists, the core has accumulated its maximum residual flux, and additional impulses serve only to provide a recycling from this point as indicated by the neutral current which began to increase rapidly at 20 microseconds and reached values well in excess of the normal magnetizing current for the unit. Note also that the applied voltage wave shape was changed slightly because of the relatively heavy current drain on the impulse generator in the vicinity of 100 to 180 microseconds.

To accentuate the magnetization phenomena, long-tail voltage waves (1.8x265 microseconds) were applied to the winding. Tracings of consecutive voltage and neutral current waves are shown in Figs. 5(A) and 5(B) for the 50% voltage level. These waves saturated the core, as evidenced by the tremendous increase in neutral current and the severe drop in impulse generator voltage on other than the first application at the 50% voltage level. The fact that the neutral current peaks occur in the vicinity of zero applied voltage indicates that the magnetizing current component was dominant.

The time integral of the first applied voltage wave in Fig. 5(A) is approximately

Fig. 6. Schematic diagram showing effect of impulse waves on core which initially had maximum residual magnetism in direction opposite to that produced by impulse wave

$$800\text{ (microseconds)} \times 10^{-6} \times \frac{30{,}000}{2}\text{ (volts)}$$
$$= 12\text{ volt-seconds}$$

assuming a simple triangular shape. Since the voltage-time area for a 2,400-volt 60-cycle wave is 0.00375x2,400 = 9 volt-seconds, the impulse flux ratio is 12/9 = 1.33, which indicates that the first impulse wave was sufficient to produce a crest flux one-third greater than that produced by normal 60-cycle excitation.

From these data, it is apparent that changes in the impulse voltage and neutral current waves can be produced by changes in core magnetization and its attendant effects upon the impedance of the winding, and are not necessarily due to winding failure. This must be taken into account when analyzing the oscillograms.

Various testing procedures were investigated to minimize and control the magnetic nonlinearities, and to provide a means of distinguishing between changes due to failure, and changes due to magnetic effects. Since the transformer will usually arrive at the impulse test area in an unknown state of residual magnetization, it appeared desirable to bring the core to a known or at least a reproducible magnetic state.

The best procedure would be to demagnetize the core by gradually reducing a 60-cycle excitation voltage to zero prior to each impulse, but this necessitates access to a voltage source which might not otherwise be required or readily available in an impulse test area.

Another solution is to impulse one end of the winding with several low-voltage long-tail impulse waves sufficient to produce saturation. This constitutes a full magnetic, reproducible bias from which to initiate commercial impulse tests on the opposite end of the winding. With the core completely magnetized in a direction opposite to that in which the flux is driven by the test wave, successive impulses will drive the core towards zero magnetization as indicated in Fig. 6 rather than toward a higher value which would result if the tests were initiated with the core completely demagnetized.

To illustrate this technique, the 250-kva 2,400/4,160Y unit previously referred to was driven to maximum magnetic bias by the successive application of six 1.5x300-microsecond waves on the H_1 terminal. The applied voltage was limited to 50% of the BIL to assure no damage to the winding. Then one 50% and two 100% BIL 1.5x45-microsecond waves were applied to terminal H_1. In accordance with the usual practice, the neutral current was reduced by the ratios of applied voltages to provide direct comparison of all neutral current oscillograms on an amperes-per-volt basis.

Tracings of the applied voltage and neutral current waves shown in Fig. 7 indicated a slight difference between the neutral currents produced by the 50% and the two 100% impulse voltage applications. Even more important is the fact that the 100% neutral current waves had lower amplitudes than the 50% waves on an amperes-per-applied-volt basis. This, coupled with the observation of no change in the voltage wave, could not represent a typical response since a failure from winding to ground would produce a change in the voltage wave and in the characteristic shape of the current wave while a failure between parts of the winding would produce an increased rather than a decreased neutral current.

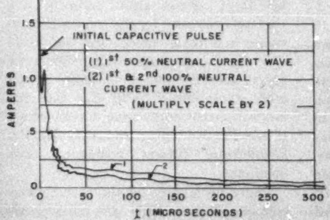
(A) APPLIED VOLTAGE WAVES



(B) NEUTRAL CURRENT WAVES

this instant differs from that observed when the core was excited by impulse from a demagnetized state. The relation of flux to magnetizing current shown in Fig. 6 is characterized by a rapidly increasing slope of the hysteresis loop; therefore, when impulse excitation reduces the flux, a point is reached where additional reduction (ϕ_{C3} to ϕ_{R3} in Fig. 6) requires very little increase of magnetizing current (I_3 to I_4) and successive impulse currents remain essentially unchanged. The primary advantage of this technique therefore results from an ability to reproduce the magnetic state of the core coupled with the relative insensitivity of the maximum magnetizing currents to repeated applications of impulse voltage while neutral current sensitivity to impulse failures is preserved.

To determine the degree of neutral current changes produced by a failure as compared to the small differences noted when the reverse remanence method is used, the core was fully magnetized in a reverse direction by the method described, and then a reduced voltage full wave (50% BIL) was applied to the opposite terminal.

Tracing 1 in Fig. 8 show the voltage and neutral current wave shapes under this condition. At this point a 1-turn short circuit was placed about the core leg over the high-voltage winding to simulate a turn-to-turn fault. A 100% BIL full-wave test was then applied, and tracings marked 2 in Fig. 8 show the voltage and neutral current wave shapes. The tremendous increase in neutral current due to the short-circuit compared to the small neutral current shift shown in Fig. 7 due to magnetization changes in the core demonstrates quite effectively that if failure of the insulation occurs or is present during the 100% full-wave test, the change in neutral current will be of an entirely different order than that due to core magnetization effects.

Conclusions

1. Changes in neutral current wave shapes between consecutive impulse tests on a transformer with perfectly good insulation can be attributed, in certain cases, to cumulative magnetization effects in the core.

2. The effect of core magnetization on the neutral current wave shape is likely to be more prominent on a low-voltage winding (e.g., 2,400 volts) than on a higher voltage winding (e.g., 15 kv) because of a higher impulse flux ratio at the lower voltage ratings.

3. The effect of core magnetization on the neutral current wave shape is likely to be more prominent on a transformer having a core with a lower exciting current due to the lack of air gaps in the magnetic circuit.

4. The effects of core magnetization on the neutral current wave shape can be minimized either by demagnetizing the core with 60-cycle excitation prior to each impulse or by first applying several low-voltage long-tail impulse waves to one terminal, thus driving the core to full saturation.

5. Although a small difference in wave shape may still exist in either of the procedures suggested in paragraph 4, a fault equivalent to a 1-turn short circuit will cause a change in the neutral current wave shape in the order of 20 to 100 times that caused by residual build-up by consecutive impulse tests.

6. When an appreciable amount of flux is produced by an impulse wave, a magnetostrictive noise is produced in the core which may be misconstrued as an indication of insulation failure.

Appendix I. Calculation of Impulse Voltage Time Integral

Eaton and Gebelein[2] propose for a typical impulse wave the equation

$$e=A(\epsilon^{-(\alpha-\beta)t}-\epsilon^{-(\alpha+\beta)t}) \tag{9}$$

where A, α, β are tabulated for various wave shapes.

Accordingly, the time integral of a standard 1.5 x 40-microsecond voltage wave is $53.8 \times 10^{-6}E_t$ volt-seconds, or

$$1.35E_t t_t \times 10^{-6} \tag{10}$$

where

E_t = impulse crest, volts
t_t = time to one-half of voltage crest in microseconds, according to the standard definition

Then, according to the general law of induction

$$\phi=\frac{-10^8}{N}\int_0^t e\,dt \tag{11}$$

the total increment of flux produced by a single impulse becomes

$$\phi_t=135\frac{E_t t_t}{N} \text{ lines of flux} \tag{12}$$

where N = number of active turns impulsed.

The time integral of an impulse wave may also be approximated by assuming the voltage crests in zero time, and that the wave decays exponentially. In this instance

$$e=E_t\epsilon^{-t/T} \tag{13}$$

For a 40-microsecond wave, the time integral becomes

$$\phi_t=145\frac{E_t t_t}{N} \tag{14}$$

A reasonable estimate for rapid calculation would be obtained by averaging equations 4 and 6 to obtain

$$\phi_t=140\frac{E_t t_t}{N} \tag{15}$$

where

E_t = crest volts
t_t = time in microseconds to $E_t/2$
N = total number of active turns under impulse

◆

Discussion

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The authors' results clearly point out that changes in neutral current waves obtained during impulse tests on transformers are caused by changes in the impedance of the transformer. These changes, however, may not necessarily be due to failures, but can be caused by the nonlinearity of the magnetic circuit. Once recognized, of course, the procedure of testing suggested by the authors will give variations in neutral current waves which are minute compared to the variation caused by even a 1-turn fault.

It is clear that great care must be used in the interpretation of current wave-shape variations lest a perfectly good transformer may be rejected in test, although the cause of the deviation was the reaction of the physical constant of the transformer rather than a failure. During the tests the neutral resistor used to measure the winding current was paralleled by a capacitor to reduce the initial high-capacitive peak to tolerable values. It is important to point this out because the high sensitivity of detection is not reduced, as clearly indicated in Fig. 8.

P. A. Abetti (General Electric Company, Pittsfield, Mass.): Heretofore it had been generally assumed that transformers show a linear behavior when subjected to impulse voltages. This conclusion is based mostly on experimental evidence[1,3] rather than on theoretical analysis of the effect of the core steel within the frequency and flux density ranges of interest. For instance, good oscillograms proving the linearity of the transformers tested are given in reference 3. All these tests were made with power rather than with distribution transformers. Theoretical and experimental studies of the effect of the iron core have been made.[4-8] Karasev and Margolin conclude that it may always be assumed that the permeability is constant and, for most practical purposes, equal to infinity. The same assumption is employed by Heller and Veverka who obtain good agreement between calculated and measured frequencies of an experimental winding with isolated neutral consisting of identical coils varying in number from 5 to 20.

This generally accepted linearity leads to three extremely important conclusions for the calculation and measurement of impulse voltages in transformers.

1. The impulse response does not depend upon the number and polarity of the impulse waves to which the transformer has been subjected previously, i.e., unless a failure occurs, the transformer has no memory for impulse tests.
2. The impulse response depends only upon the shape, not upon the magnitude of the applied voltage wave.
3. The impulse response does not depend upon the applied power-frequency voltage.

In fact, the response obtained with applied voltages of the order of 1,000 volts by means of the transient analyzer is assumed to be equal to the response during commercial impulse testing or in the field with impulse voltages up to or larger than 1,000,000 volts and, eventually, with full power-frequency voltage.

The authors have clearly shown the limitations of conclusion 1 for certain ratings of distribution transformers and how to overcome such limitations. The question might now be raised whether conclusions 2 and 3 still hold as assumed heretofore, and the following considerations will be of help.

In the standing-wave theory the impulse response of a winding depends upon: the modes of oscillation of the winding (wave shapes and natural frequencies); and the difference between the initial and final distributions, which determines the amplitude of these modes.

If the core is nonlinear, its nonlinearity must affect either the modes of oscillation or their amplitudes to influence the impulse response. The initial distribution depends mainly upon the transformer capacitances, while the final distribution is almost linear. Changes in the core permeability could only alter the small deviations from linearity of the final distribution, with negligible effects on the mode amplitudes. More important are the effects of the core on the wave shapes and frequencies of oscillation.[6,7] If the neutral of the winding is isolated, there is magnetizing flux in the iron core, and a decrease in permeability will have two effects: the values of the lower natural frequency will be increased, while the higher frequencies will remain practically the same; and the wave shapes of the lower harmonics become more peaked, and the corresponding maximum gradients are increased.

For a 1.5x40-microsecond applied wave, an increase of the fundamental frequency will increase somewhat the maximum voltages to ground. In fact, these maximum voltages usually occur after one semiperiod of the fundamental. The shorter this period, the smaller the decay of the applied wave and, therefore, of the axis of oscillation, which corresponds to the final distribution. On the other hand the changes in wave shape will reduce the amplitude of the fundamental and this will counteract in part the aforementioned effect. The increased gradients of the lower harmonics may increase the voltages between relatively distant parts of a winding, e.g., across 10- to 50-per-cent winding. When the neutral of the impulsed winding is grounded, as in the great majority of practical cases, the natural modes of the winding do not cause any magnetizing flux. The path of the leakage flux for these modes is mostly in air and, therefore, the effect of the core on the wave shapes and natural frequencies is much smaller for grounded than for isolated neutral. In all cases the voltages between coils and between turns of the impulsed winding are not affected at all by the behavior of the core. In fact, these voltages are determined essentially by the higher harmonic modes of the winding. In a recent analysis by field theory,[8] it was shown that the presence of an iron core with infinite permeability influences the surge performance of a coil only within the range of the lower harmonics. It follows that this effect will be less for a core with finite but constant permeability and even less will be the effect of variation of the permeability.

Further evidence to substantiate these conclusions has been obtained by tests on electromagnetic models of power transformers. It will be recalled[4] that these models reproduce correctly the nonlinear properties of the iron core, since the values of B, H, and μ are the same at corresponding points and at corresponding times in the original and in the model. Since transformers behave linearly for most impulse phenomena, this important characteristic of electromagnetic models is made use of only in special investigations. For instance, the natural frequencies of the high-voltage winding of a 3-phase 30,000-kva transformer model were measured as a function of the applied voltage. It was found that the fundamental frequency with isolated neutral showed a 20-per-cent change, while the higher harmonics with isolated neutral and all natural frequencies with grounded neutral showed changes from 1 to 4 per cent of the order of accuracy of the measurements. Similar results were obtained with a model of a 667-kva single-phase transformer.

It may be concluded, therefore, that the nonlinear behavior of the core, evidenced by the authors for certain types of distribution transformers, will affect very little the oscillatory components of the impulse response. There will be no changes in the voltages across small parts of the winding, and the changes in the voltages to ground and across large parts will be small. It may be also concluded that tests with the transient analyzer and with the impulse generator reproduce satisfactorily in all cases the conditions encountered in the field.

M. F. Beavers, J. E. Holcomb, and L. C. Leoni: It is interesting to note that Mr. Abetti's theoretical studies indicate that the nonlinear behavior of certain transformer cores will have very little effect on the impulse response of the transformer.

As Mr. Hagenguth points out, great care must be used in the interpretation of current wave-shape variations lest a perfectly good transformer be rejected in test. It was suggested that the test code be studied by the appropriate committee to consider modifications which would recognize the change in the applied voltage and neutral current wave shapes caused by magnetization of transformer cores during impulse testing.

Power Distribution System Parameters

A. H. KIDDER
FELLOW AIEE

J. H. NEHER
MEMBER AIEE

THE POWER distribution engineer is frequently confronted with the need to appraise effects upon the distribution system such as would be caused by the supply of singular loads, or by proposed modifications of distribution practice relating to circuit and substation sizes, power factor (pf) correction, a change in distribution voltage, or a change in the limits of voltage regulation. For rate-making purposes he is occasionally required to appraise the costs associated with the supply of existing and possible new types of loads and customers.

The effects of each load extend through all of the circuits which, together, comprise the related power distribution system. Among other things, therefore, consistent appraisal requires evaluating directly, according to one consistent method, the effect of each load upon both the length and the weight of conductors needed at each distribution voltage level; as well as the load and the number of customers supplied per circuit, per transformer, and per substation. This paper therefore has been prepared to summarize the development of a method which holds promise of achieving the desired results, by dealing with the distribution circuit as a functional entity and in terms of its natural parameters.

List of Symbols

a = fixed component of unit cost
a_c = applying to a circuit, cost units per conductor foot
a_t = applying to a transformer, cost units per transformer
A = conductor size, circular mils (CM)
α = phase angle of voltage loss in a circuit
α_p = applying to principal lateral
α_r = applying to riser branch
b = incremental component of unit cost
b_c = applying to a circuit, cost units per pound of conductor
b_t = applying to a transformer, cost units per kilovolt-ampere (kva) of load
b_p = capitalized cost of power, cost units per watt
β = equivalent load density, thousands of kva per square mile
C = unit cost
C_c = applying to a circuit, cost units per kva
C_t = applying to a transformer, cost units per kva
Δd = length of a unit section of circuit, feet
d = distance between two points, feet
d_p = from supply point to end of principal lateral
d_r = from supply point to end of riser branch
D = total circuit length, feet
δ = current density, amperes per 1,000 CM
E = effective voltage to neutral
f = lateral distance between unit loads, feet
F = voltage adjustment factor as developed in Appendix III
F_p = applying to principal lateral
F_r = applying to riser branch
i = phase current per unit load, amperes
i_0 = applying to an existing design
1,000 I/A = current density, amperes per 1,000 CM
I_s = motor starting current, amperes
j = phasor operator $\sqrt{-1}$
K = constant resistive voltage loss per foot in conductor of a size proportional to its ampere load
K_0 = applying to an existing design
K_p = applying to laterals
K_r = applying to riser branches
L = total load delivered by a circuit in kva
(LF) = annual loss factor of a circuit
m = ampere feet per phase conductor between two points
m_p = from supply point to end of principal lateral
m_r = from supply point to end of riser branch
M = total ampere feet per phase conductor of circuit
n = a number equal to half-length of a riser branch divided by s
N = number of conductors in a circuit, including the neutral
N_p = number of phase conductors
p = power loss per phase conductor, watts
p_p = from supply point to end of principal lateral
p_r = from supply point to end of riser branch
P = total power loss per phase conductor, watts
ϕ = equivalent customer density, thousands per square mile
q = a number equal to the half-length of the principal lateral divided by f
Q = number of unit loads per unit
R = circuit resistance, ohms per conductor foot
ρ = conductor resistivity, CM ohms per foot
s = distance between lateral branches, feet
S = unit size
T_i = effective transformer current ratio, primary/secondary, including the effect of a different number of phase on each side
T_v = effective transformer voltage ratio, primary/secondary
$\Delta\theta$ = change in phase angle along a circuit (Fig. 1)
θ = angle by which currents lags the effective phase-to-neutral voltage, degrees
U = unit load, kva
v = permissible voltage loss of a circuit, per cent (%)
v_s = voltage dip due to motor starting, %
V = voltage loss per phase conductor between two points, volts
V_i = component of V in phase with the current
V_q = quadrature component of V
V_t = voltage loss in a transformer (referred to the secondary)
W = total weight of one phase conductor, pounds
X = circuit reactance, ohms per conductor foot
X_s = circuit reactance applicable to motor-starting currents, ohms per conductor foot
y = the number of a lateral counting from the extremity of a riser branch
Z = circuit impedance, ohms per conductor foot

The use of the prime (′) indicates a successively higher circuit level.

General Considerations

The principal classes of distribution system components are conductors with their associated insulation and structures; also substations, transformers, switchgear, regulators, pf corrective equipment, and metering installations. The effect of size S upon the installed cost C for an assembly of a given class seldom requires evaluating coefficients for more than the first two terms of the following complete representation

$$C=a+b_1S+\ldots+b_nS^n \tag{1}$$

It is important, however, to observe that the fixed, or a component of cost is usually appreciable. In the case of conductors, for instance, the a component of cost, which is independent of conductor size, includes practically the whole cost per foot for the associated rights of way and structures such as poles, or towers, or conduits and manholes. Hence, consistently representative distribution system parameters must permit determining the quantity as well as the size of each unit assembly under the given conditions.

The development of distribution circuit parameters begins with the prerequisite that the voltage loss between the first and last loads distributed from a common supply point must not exceed some established design limit. For the purposes of practical generalization, the following six assumptions have been made:

1. A large number of equal loads, located on rectangular properties of identical size.
2. Rectangular intersections between the through streets and the cross streets.
3. Lateral and riser main conductors erected along routes respectively parallel

---

Paper 55-19, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted September 8, 1954; made available for printing November 8, 1954.

A. H. Kidder and J. H. Neher are with the Philadelphia Electric Company, Philadelphia, Pa.

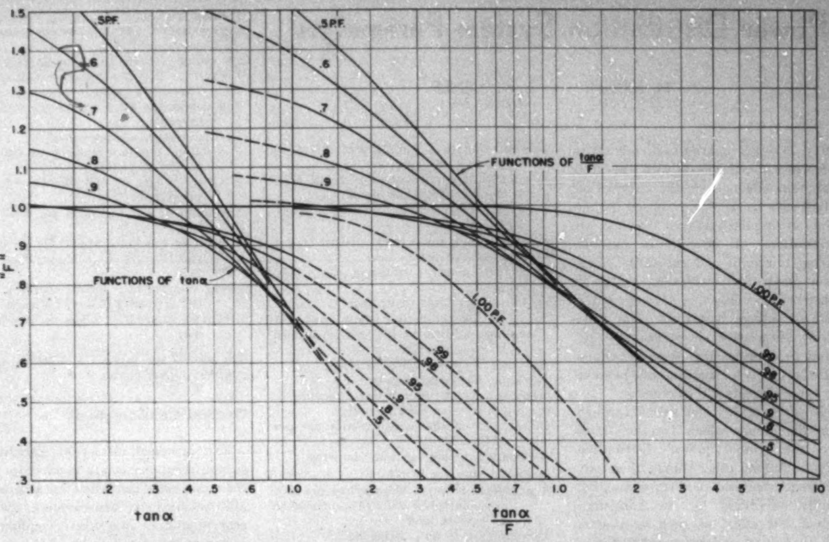

Fig. 1. Voltage adjustment factor F as functions of tan α or (tan α)/F, and pf

to the through streets and the cross streets. These are tentatively assumed to be consistently interconnected, so as to form one continuous electrical network throughout the whole area to be served.

4. Each distribution circuit includes one supply point complete with all essential equipment and accessories, plus all conductors carrying the load it distributes to the various points where it is delivered to customers, or to the supply points of other circuits in the system of which it is a part.

5. For illustrative convenience, it is assumed that the distribution system can be completely represented in terms of circuits operating at but three distribution voltage levels which will be consistently designated as the secondary-, primary-, or high-voltage levels.

6. As a practical first step, the conductor cross section is assumed proportional to the ampere load, but with the explicit understanding that the natural relationship must be determined before this analysis is considered complete.

The foregoing assumptions have the advantage of limiting the initial investigation exclusively to considering the singular effects of individual loads. After these effects have been evaluated, it will be appropriate to undertake an accounting for the characteristics peculiar to the community, as determined in part by diverse street configurations, diverse land occupancy, diverse loads, and diverse load-coincidence relationships.

Voltage Loss Characteristics

The permissible voltage loss is the amount by which the voltage delivered to the most remote load on a circuit may be less than that supplied to the circuit. This is a function of the effective impedance, the current flowing, and also the phase relationship between current and voltage.

The electrical resistance is inversely proportional to the conductor size and therefore is assumed tentatively to bear an identical relation to the load current. On the other hand, the reactance component of electric circuit impedance is determined by the spacing between conductors having different polarities, by the magnetic permeability of the conductor material and, to some extent, by the conductor diameter. Increases in conductor size decrease the reactance somewhat, but this is an effect which may be neglected in the present analysis because some overstatement of the reactance is permissible. This permits the assumption that the reactance is that for the smallest practicable conductor size at the given conductor spacing. The conductor spacing is essentially fixed by the operating voltage of the circuit, and the choice of open-wire or cable construction. Hence, the effective reactance per conductor is largely independent of its load in amperes. However, there are cases, particularly in underground cable circuits, where the required total conductor area of the circuit is divided between a number of parallel paths or cables along the given route, and the effective reactance is then inversely proportional to the number of parallel paths and the total load in that part of the circuit.

Consider, now, a section of single path main Δd-feet long and carrying I amperes of current per phase, in a physical arrangement of conductors which has an effective resistance of K/I ohms per foot and an effective reactance of X ohms per conductor foot. The impedance of the conductor becomes the phasor

$$Z=\frac{K}{I}+jX \text{ ohms per conductor foot} \qquad (2)$$

and, taking current as the reference phasor, the voltage loss in the section becomes

$$V=V_i+jV_q=I\Delta d\left(\frac{K}{I}+jX\right) \qquad (3)$$

$$=K\Delta d+jXI\Delta d \text{ volts per section}$$

The quantity K appearing in these equations represents the constant resistive voltage loss per foot in conductors having sizes proportional to their ampere loads. If the corresponding conductor area is A in CM and ρ represents the resistivity of the conductor in CM ohms per foot

$$K=\frac{I}{A}\rho \text{ volts per foot} \qquad (4)$$

$$=\frac{12I}{A} \text{ for copper conductors}$$

It will be seen from equation 3 that the voltage loss consists of two components: one, a function of the Δd-foot length of the section; the other, a function of the $I\Delta d$ ampere feet in the section. By extension, to include a number of adjacent sections having differing values of I, which change with each additional unit load picked up, it will be seen that the over-all voltage loss between any two points is a composite function of the total distance d and the m-ampere-foot total per conductor included.

In the symmetrical distribution system assumed, each unit load will be a constant of i amperes per conductor. The m ampere feet will equal the sum of the products of i by the respective circuit distances to the unit loads distributed by the circuit. The evaluation of m will be considered in due course. Meanwhile, the voltage loss between the point of supply and any point in the distribution circuit may be written as

$$V=Kd+jXm \text{ volts} \qquad (5)$$

while, for a previously installed main in which the conductor area was originally designed for a unit load current of i_0 amperes with conductors having a voltage loss of K_0 volts per foot, equation 5 becomes

$$V=(K_0i/i_0)d+jXm \text{ volts} \qquad (6)$$

The assumption of uniform current density is a useful device for determining the average conductor size needed in any situation. The fact that practical considerations discourage frequent changes in conductor size need cause no concern, because practical deviations from rigorous observance of uniform current density have little effect upon voltage loss. In fact, it is often useful to assume a uniform conductor size having the same total weight as if it had been "tapered" to operate everywhere at uniform current density. The average size would be the same in either case, and identically related to the load.

For a uniform conductor size having an effective resistance of R ohms per conductor foot, the voltage loss is given by the expression

$$V=m(R+jX) \text{ volts} \qquad (7)$$

If v represents the permissible voltage loss in % of the nominal voltage E, and θ represents the pf angle of the load, the following approximate relationship will exist for a circuit having uniform current density

$$\frac{vE}{100}=Kd\cos\theta+mX\sin\theta \text{ volts, approximately} \qquad (8)$$

For convenience, equation 8 may be replaced by

$$\frac{vE}{100}=\frac{Kd}{F} \text{ volts} \qquad (9)$$

where F is a function of both θ, the pf angle of the load, and α, the effective phase angle of the circuit impedance; the value of α being such that

$$\tan\alpha=mX/Kd \qquad (10)$$

Similarly, for a circuit having uniform conductor size throughout

$$\frac{vE}{100}=m(R\cos\theta+X\sin\theta), \text{ approximately} \qquad (11)$$

$$=mR/F \text{ volts} \qquad (11A)$$

where F is a function of

$$\tan\alpha=X/R \qquad (12)$$

Curves of F for various values of pf are given in Fig. 1, as functions $\tan\alpha$ or $(\tan\alpha)/F$. As indicated in Appendix III, these curves contain a correction for the quadrature component of voltage drop which is not compensated for in equations 8 and 11.

Elementary Distribution Circuits

The natural method of installing low-voltage, or secondary lateral mains in an urban community is to route them either along, or parallel to, the through streets. The distance between such lateral mains will be roughly equal to the s-foot distance between the through streets. Under the assumption of equal loads, each in an equal area, the points of connection to the mains may be generalized as a series of unit loads equally spaced at intervals of an f-foot distance along the laterals.

Such a system is shown in Fig. 2, in which the unit loads are indicated as dots along the lateral mains and the supply points are indicated by circles. Riser mains are also shown, perpendicular to and interconnecting the laterals. The over-all effect of interconnecting the laterals and risers is to permit the maximum practical use of each supply-point by forming a uniform and electrically continuous distribution network.

As one considers the symmetry of the network described, it will be observed that there will be certain points on each of the laterals and risers, at which there will be no current flow. The limits of the area bounded by such points of no-load transfer are indicated by the dashed lines of Fig. 2, from which it is seen that the energy fed through each supply-point is distributed throughout a diamond-shaped area. It is also apparent that the load and voltage distribution within each diamond would not be affected in any sense, if the diamond were arbitrarily separated from the network and operated independently as a circuit having the loads shown in the branch type of circuit in Fig. 3. It will be seen that the load at each extremity of the

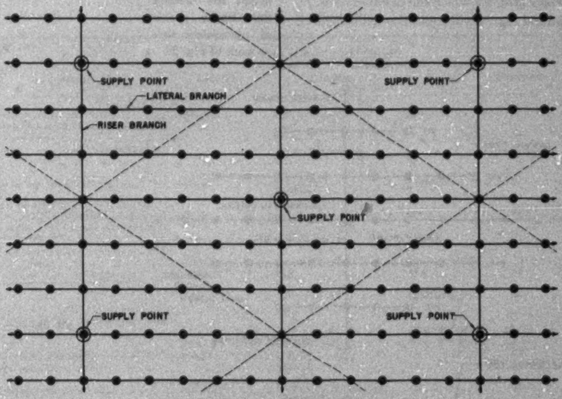

Fig. 2. Elementary distribution network

principal lateral and riser branches is but one-fourth of the unit load, since the loads located at these points are fed symmetrically from four directions. Similarly there will be a half-unit load at the extremities of each of the other laterals.

Consider the half-length of the principal lateral to be qf feet and the half-length of the riser branch to be ns feet in Fig. 3, as limited by the requirement that the permissible voltage loss shall not be exceeded. This requirement will have been satisfied approximately, if the total voltage loss between the supply point and the extremities of both the principal lateral and riser branches is held within the permissible limit. As indicated in equations 5, 6 and 7 the voltage loss will be a function of d_p and/or m_p for the principal lateral and d_r and/or m_r for the riser branch.

Under certain conditions, permissible voltage drop or other considerations may indicate that it is impractical to utilize riser branches. In this case the network reduecs to a system of laterals only, and each supply point will serve a lateral type of circuit, as illustrated also in Fig. 3. In this case it will be seen that the effective area served by each circuit is rectangular in shape.

Primary- and High-Voltage Distribution Circuits

It will be apparent that the supply points of a low-voltage or secondary grid will include transformers fed from a similar primary grid. In this case the total load of each secondary circuit and its losses becomes the unit load of the primary grid, for which the distance between lateral mains will equal the half-length of the secondary riser branches, being

$s' = d_r$ feet, the half-length of the branch-type secondary riser branch, or
$= s$ feet, the distance between streets for a lateral-type secondary (13)

and the lateral distance between unit loads on the primary will be equal to twice the half-length of the longest, or principal lateral in the secondary-circuits which it supplies, being

$f' = 2d_p$, the length of the principal secondary lateral (14)

Further, it will be noted that for alternate lateral mains the locations of the loads picked up are displaced laterally by a distance of $f/2$ from the positions of the loads on adjacent laterals. The equivalent circuit for such a grid assumes two forms as shown in Fig. 4, depending upon whether the parameter n represent an even or an odd number of laterals.

Likewise, each primary-branch circuit may include a unit-type substation, which is fed in turn from a similar type of high-voltage grid. On the other hand, construction economy may favor reducing high-voltage conductor mileage by installing larger substations and "radial-type" primary feeders to permit supplying several primary-branch circuit loads per substation. However, whether it be high-voltage branch circuit supply or primary-voltage, radial-feeder supply, the circuit routes must run along or under streets; hence the vertical distance s and the lateral distance f between loads picked up will be given by expressions identical to equations 13 and 14, in which d_r and d_p have values as determined for the grid being supplied.

For the radial type of primary circuit, the maximum feeder length (Fig. 5), is determined simply by the impedance and the load. It is, therefore, evident that the area served in this case will have the shape of a diamond whose parameters qf and ns will be equal. The use of feeder voltage regulators permits the use of longer feeders, to serve when desirable a larger area and load from such a circuit.

Circuit Parameters

It is now practical to determine the total number Q of unit loads served, the total length D feet of the circuit, the total ampere feet M, and the power loss P in watts per conductor, in terms of the foregoing relationships. The total weight of one phase conductor may be determined from the ampere feet M, by the following relationships in which w represents the

Fig. 3 (below). Equivalent circuit for one supply point in the elementary network of Fig. 2

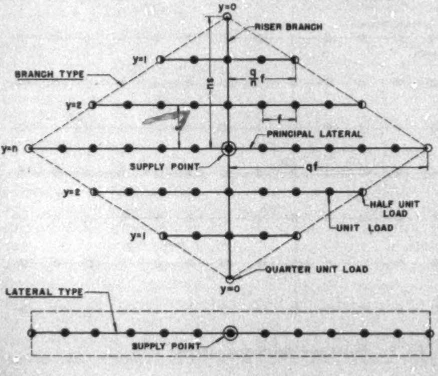

Fig. 4 (right). Equivalent supply circuit for feeding the supply points of elementary network of Fig. 2

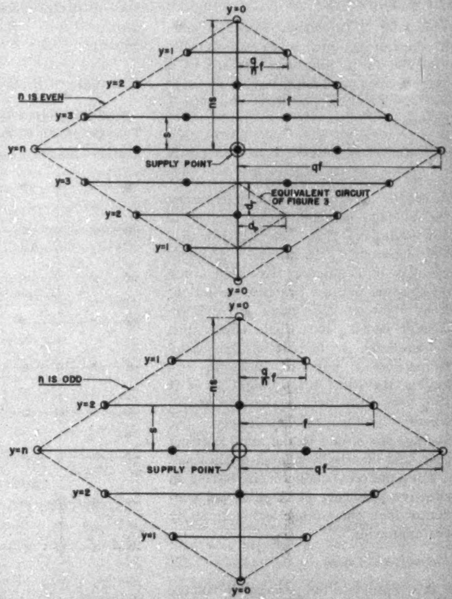


weight of the conductor in pounds per CM foot. For a circuit having a uniform current density

$$W = w_p M/K \text{ pounds per conductor}$$
$$= 36\times10^{-6}\, M/K \text{ for copper} \quad (15)$$

and for a circuit having a uniform conductor size throughout

$$W = wAD = w_p D/R \text{ pounds per conductor}$$
$$= 36\times10^{-6}\, D/R \text{ for copper conductors} \quad (16)$$

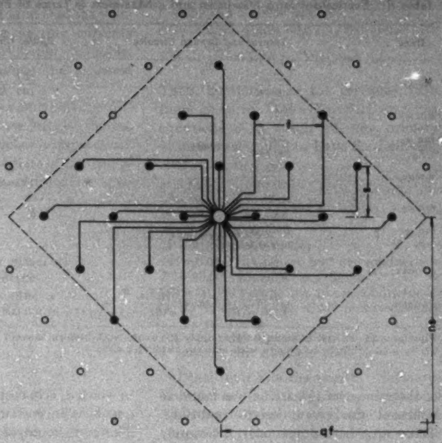
The branch, lateral, and radial type of circuits discussed are analyzed in Appendixes I and II, from which it will be seen that general parameters may be derived which are qualitatively identical for any type of circuit and voltage level. These are given in Table I.

Equivalent values of K in terms of R may be obtained from equations 8 and 10 after making the proper substitutions for d and m from Table I. These equivalent relationships are also given in Table I. In the case of a branch type of circuit it will be noted that the equivalent value of K_p for the lateral branches, equation 28, differs from K_r for the riser branch, equation 29. For cost analysis, however, it is sufficient to use the average relationship given by equation 30, which is obtained by simultaneously solving equations 26 and 27.

The values of q and n appearing in the equations of Table I are subject to certain limitations. Field conditions in a city, for instance, will require that n be an integer, since ns is a multiple of the distance between the streets along which the lateral branches are run. For a branch type of system, qf should be related similarly to the distance between the transverse streets which will carry the riser branches. For the radial system as shown in Fig. 5, it will be evident that b must be an integer and that q must be a multiple of one half, since qf must be a multiple of $f/2$.

Also, as previously indicated, the values of q and n must be such that the permissible voltage loss to the extremity of the principal lateral or riser branch shall not be exceeded. By substituting equations 14, 19, 21 and 22 in equations 9 and 11, expressions are obtained for q-maximum and n-minimum, as given in Table II. Since n-max will depend upon q, the solution for q should be made first. In the case of lateral and branch circuits equations 32 and 34, the parameter tan α on which the factor F depends is itself dependent upon q or n, which in turn involve F. A solution for F may be effected by use of equations 32(A) and 34(A) involving the parameter (tan α)/F.

Fig. 5. Radial-type supply circuit



Curves of F are derived in Appendix III and given in Fig. 1, as functions of pf and tan α, or (tan α)/F.

Under certain conditions, the values of q and n thus obtained may result in a value of total current which exceeds the permissible load for a particular part of the circuit. In this case the values of q and n should be reduced observing the permissible current limitation, as well as that of approximately equal voltage losses to the respective extremities of the circuit.

For calculating the total weight of conductors, it has been necessary to assume with theoretical rigor that the conductor size everywhere in the circuit is exactly proportional to the amperes carried. The average conductor size thus derived is therefore proportional to the load, and it has been explained that the theoretical tapering of conductor sizes if of no practical significance, except as a device for determining the average size. Henceforth, the principal controlling factor is voltage loss which can be handled as rigorously and far more readily in terms of a more practical construction, such as the utilization, throughout the full length of each lateral and riser in the circuit, a uniform conductor cross-section

Table I. Distribution Circuit Parameters

Item	Type of Equivalent Circuit: Lateral	Branch	Radial	Equation
Q = number of unit loads	$2q$*	$2qn$	$2qn$	17
d_p = half length of principal lateral in feet	qf	qf	qf	18
d_r = half length of riser branch in feet		ns	ns	9
D = circuit length in feet	Qf	$Q(f+s/q)$	$\frac{Q}{3}(qf+ns)$	20
m_p = ampere feet per conductor in half of principal lateral	$q^2if/2$	$q^2if/2$	qif	21
m_r = ampere feet per conductor in half of riser branch		$n^2isq/3$	ins	22
M = ampere feet per conductor in circuit	$qfQi/2$	$(qf+ns)Qi/3$	$(qf+ns)Qi/3$	23
P = watts loss per conductor	MK	MK	MK	24
	$Qi^2Rq^2f/3$	$Qi^2Rq\left(\frac{qf}{6}+\frac{2n^2s}{5}\right)$	$Qi^2R(qf+ns)$	25

Equations 24, 26, and 31 through 34(A) apply to circuits with uniform current density and equations 25, 27, 35, and 36 apply to circuits with uniform conductor sizes.

of the same average size as was found to represent the given design conditions. There may be sections near the supply point, particularly in the higher voltage circuits, in which somewhat larger conductors will be needed in order to prevent overheating. However, such high-current sections can be identified readily, and a larger conductor provided if required.

Cost Considerations

It can be shown that the installed cost of a lateral or riser main may be expressed in the general form

$$C_c=\frac{DN}{L}\left(a_c+b_c\frac{W}{D}\right)\text{ cost units per kva}\quad(37)$$

in which the constants a_c in cost units per conductor foot and b_c in cost units per pound of conductor are dependent upon the type of construction involved. L represents the distributed load in kva, and N the number of phase and neutral conductors. If the neutral is of reduced size, the weight factor in equation 35 should be reduced accordingly. This cost includes conductors, devices and the allocated portion of poles and fixtures, or rear busses in the case of the secondary.

If U represents the unit load in kva at each secondary-service tapoff, and Q is the number of loads supplied

$L=QU$ kva for the secondary-circuit

whence

$L'=LQ'$ kva for the primary circuit
$L''=L'Q''$ kva for the primary-supply-circuit
(38)

Similarly for a transformer installation

$$C_t=\frac{1}{L}(a_t+b_tL)\text{ cost units per kva}\quad(39)$$

in which a_t is in cost units per transformer and b_t is in cost units per kva of load. This cost should, of course, include installation cost as well as the material costs of the transformer and its accessories, such as lightning arresters and fuses.

The capitalized cost of line losses may be determined from the following expression

$$C_{cl}=b_p(LF)N_p\frac{P}{N}\text{ cost units per kva}\quad(40)$$

in which b_p represents the capitalized cost of power in cost unit per watt, (LF) is the annual loss factor of the circuit, N_p the number of phase conductors, and P the watt power loss per phase conductor at the time of maximum load.

Similarly for a transformer

$$C_{tl}=5b_p[1+3(LF)]\text{ cost units per kva}\quad(41)$$

Equation 41 is predicated upon 0.5% iron losses and 1.5% full-load copper losses in the transformer.

Effect of Motor Starting Currents

Heretofore, we have not considered the voltage dips caused by 120-volt fractional horsepower motor-starting currents. The effect is almost entirely restricted to the secondary circuit and distribution transformer, and is greatest when caused by the starting of a motor at the end of the principal lateral. Since the secondary circuit is usually 3-wire single phase, this voltage drop involves the neutral conductor as well as one of the phase conductors.

If the neutral and phase conductors have a resistance of R ohms per foot, and if the transformer impedance be taken at a nominal value of $1.8+j2.7\%$; and I_s is the motor-starting current in amperes at 0.5 pf, we may find the resultant voltage dip v_s in % by analogy to equation 10. Thus

$$v_s=100\frac{I_s}{E}\left[qf(R+1.73X_s)+0.032\frac{E}{Qi}\right]\%\quad(42)$$

in which X_s represents the reactance in ohms per foot between the neutral conductor and the phase conductor involved.

For secondary circuit conductors having uniform cross section equal to the average size which satisfies the given conditions of load and voltage loss, the relationship between K and R will be that given in equation 28 of Table I. Thus for a secondary designed to operate at uniform current density

$$v_s=100\frac{I_s}{E}\left(2\frac{fK}{i}+1.73qfX_s+0.032\frac{E}{Qi}\right)\%\quad(43)$$

If a permissible value is established for v_s, the maximum permissible values of R or K are

$$R\text{-max}=0.01\frac{E}{qf}\left(\frac{v_s}{i}-\frac{3.2}{Qi}\right)-1.73X_s\text{ ohms per foot}\quad(44)$$

$$K\text{-max}=\frac{0.005E}{f}\left(\frac{v_si}{I_s}-\frac{3.2}{Q}\right)-0.866qiX_s\text{ volts per foot}\quad(45)$$

It will be noted that the neutral conductor resistance has an important effect on the voltage dips accompanying line-to-neutral motor-starting current surges. This effect gives added support for the usual practice of utilizing identical neutral and phase-wire sizes in secondary circuits.

Illustrative Example

To illustrate the composite effect of the relationships so far established, it is desired first to determine what would be the cost per customer for overhead secondary circuits and primary branches, in a system designed to satisfy certain assumed conditions; then, to observe how the cost would be affected respectively by moderate deviations from the assumed design conditions. The illustration need not be carried further at this stage because this will be sufficient to illustrate all of the principles involved.

For this purpose, let us consider a large group of identical single phase customers, each having noncoincident maximum demand of 1 kva at 0.95 pf, in an area where the property lines and street configurations are as illustrated in Fig. 6; to be supplied by a 3-wire 120/240-volt single-phase secondary, through 2,400-

120/240-volt distribution transformers fed by 2,400/4,160 Y primary circuits in an overhead system, having a common primary and secondary neutral and an over-all voltage spread of 10%, between the respective customers' service taps along the secondary mains.

To simplify the illustration, it is arbitrarily assumed that no special provisions for emergency breakdown service need be made, and that the single phase secondary loads are somehow balanced between the primary phases at each transformer location. The assumption of balanced 3-phase transformer loads at single-phase transformer locations has the advantage of simplifying primary-branch geometry and related calculations while maintaining the distributed load per conductor mile essentially the same as that which accompanies the normal practice of supplying adjacent single-phase loads from adjacent phases of polyphase mains. The foregoing and certain other necessary assumptions are summarized as follows:

$f=650/12=54$ feet
$s=250$ feet
$\theta=\cos^{-1} 0.95=18.2$ degrees
$U=2$ kva load at each secondary service tap-off
$i=\dfrac{2\times 1{,}000}{240}=8.3+j0$ amperes load at each secondary tap-off
$E=\dfrac{240}{2}(\cos\theta+j\sin\theta)=114+j\,37.5$ volts
$V_t=1.8+j\,2.7$, % voltage loss in the transformer
$=2.5\%$ effective at 0.95 pf
$v+v'=7.5\%$ voltage loss, total in secondaries and primaries, divided as equally as practicable
$N=N'=3$; $N_p=2$; $N_p'=3$
$K=0.012$ volts per conductor foot for copper at 10^{-3} amperes per CM
$I_s=20$ amperes and $v_s=4\%$ for 120-volt motor-starting current
$X=116\times 10^{-6}$ ohms per foot
$X_s=102\times 10^{-6}$ ohms per foot
$X'=144\times 10^{-6}$ ohms per foot
$(C_eL)/(DN)=0.123+0.31\ W/D$, cost units per secondary or primary conductor, foot-installed, complete with supports and all accessories
$C_tL=125+6.2\,L$, cost units per transformer, installed complete with accessories
$b_p=0.164$ cost units per watt; $(LF)=0.12$

By equations 31 and 32 of Table II, assuming $v=3.75\%$, it is found that $q-\max=6.6$. By equation 14 it is found that $f'=2qf=710$ feet. In this case, however, f' must be a multiple of the 650-foot length of the block as required to permit location of the primary branches along the transverse street routes. Hence the correct value becomes $q=6$ and the corresponding secondary voltage loss becomes $v=3.3\%$, which leaves a balance of $10-2.5-3.3=4.2\%$ available for allocation to the primary circuit.

By equation 41 it is found that the voltage dip due to motor-starting currents $v_s=4.2\%$ which is probably tolerable, being only slightly above the assumed limit of 4%.

Since $qf=325$ feet, or one-half the distance between transverse streets, the use of secondary-riser branches is impractical. Hence the secondary will be of the lateral type, for which it is found from the equations of Table I that

$Q=12$
$D=650$ circuit feet
$M=16{,}100$ ampere-feet per conductor
$P=193$ watts per conductor
$W=48.5$ pounds per conductor
A-average $=12/R=25{,}000$ CM (approximately no. 6 size)

and by equation 38

$L=24$ kva

Whence, by equations 37, 40, 39, and 41, the respective components of secondary circuit cost become

$C_e=11.9$ cost units per kva; $C_{el}=0.32$ cost unit per kva
$C_t=11.4$ cost units per kva; $C_{tl}=1.12$ cost units per kva

The corresponding characteristics of the associated primary branches may be found by the use of equations 13 and 14 and the following relationships

$$E'\underline{/\theta}=T_v[(1+0.005v)E+V_t] \text{ volts} \qquad (46)$$

$$i'=QiT_t \text{ amperes} \qquad (47)$$

in which V_t represents the transformer voltage loss, T_v the effective transformer voltage ratio, and T_t the effective transformer current ratio including the effect of the assumed transformation from a single-phase secondary to a 3-phase primary.

Thus, for the primary branches

$f'=650$ and $s'=250$ feet
$E'\underline{/\theta'}=2{,}360+j824=2{,}520\underline{/19.2}$ volts
$i'=\dfrac{12\times 8.3}{30}=3.3+j\,0$ amperes

Then, by the use of the pertinent relations given in Tables I and II and cost equations 37 through 41, the primary branches are found to have the following characteristics

$q'=13$
$n'=18$
$Q'=468$
$L'=11{,}200$ kva
$D'=313{,}000$ circuit feet
$M'=6.68\times 10^6$ ampere feet per conductor
$P'=80{,}000$ watts per conductor
$W'=20{,}000$ pounds per phase conductor
A' average $=21{,}300$ CM (approximately no. 7 size)
$C'_e=12.0$ cost units per kva
$C'_{el}=0.42$ cost units per kva

Upon review of the resulting primary-branch grid, it is found that an additional 8,900 feet of neutral conductor would be required for the riser branches in certain sections where there would be no secondary conductors to provide a common neutral. The cost of this neutral amounts to 0.02 cost units per kva. Thus, the total installed cost of the secondary circuit and primary-branches is 35.5 cost units per kva, exclusive of service taps from the secondary circuit to the customer's premises. The capitalized cost of power losses is also seen to be 1.86 cost units per kva, making the total cost 37.2 cost units per customer for the secondary circuit, associated primary branches and power losses.

To appraise the total cost per customer in each particular case of course, the calculations must be extended similarly, so as to evaluate the corresponding transformer component or substation component of primary-circuit cost and the higher voltage circuit costs, as well.

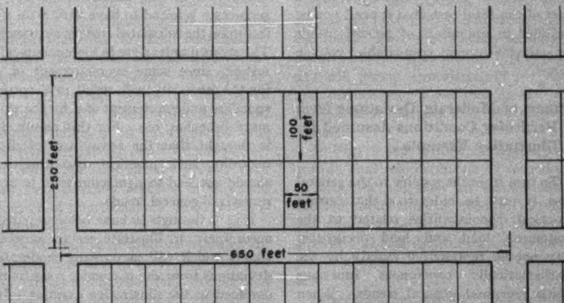

Fig. 6. Street and property lines assumed for example

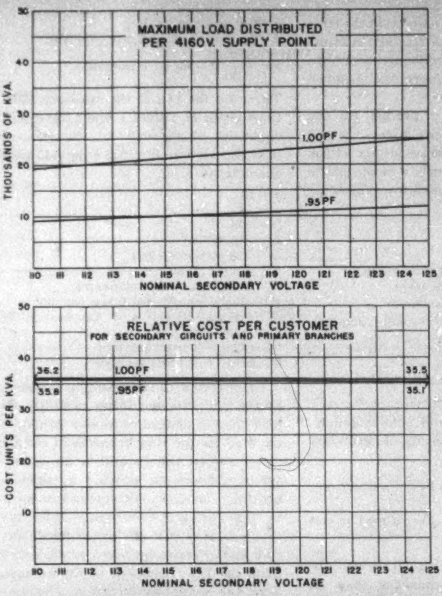

Fig. 7. Illustrative effect in new construction of nominal secondary voltage upon aerial circuit capacity and cost for 1-kva per secondary customer on a 50-by-100-foot lot, with 10^{-3} amperes per CM, 3.3% voltage loss in secondaries, 4.2% in primaries, and 2.5% in transformers

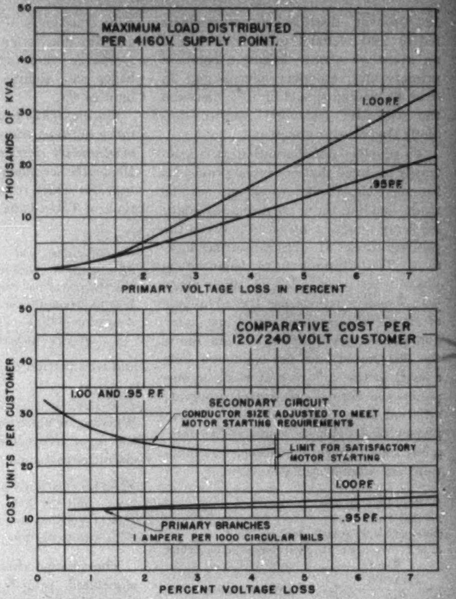

Fig. 8. Illustrative effect in new construction of voltage loss upon aerial circuit capacity and cost for 1 kva per 120/240-volt customer on 50-by-100-foot lots

These additional calculations will not be undertaken now because no new principles remain to be illustrated. It is preferred instead to consider how moderate deviations from the voltage, load density, etc., assumed for the illustration would affect the costs of the components already evaluated.

It is already apparent that the capitalized cost of power losses is so small a part of the total cost that it need not be included in appraisals of general trends for circuits having comparable voltage losses.

Effects of Moderate Deviations from Particular Conditions Assumed for Illustrative Example

To turn from the specific to the general case, it must be understood that certain practical discontinuities related to the customer's load and land occupancy may not be represented exactly by the mathematically continuous functions which represent general trends. When the customer's load, as well as the frontage and depth of his property become independent variables, it will be seen, for instance, that the expressions for q and n will almost invariably develop intermediate fractional values such as $q=6.6$, rather than the integer $q=6$ which exactly represented the conditions assumed in the illustrative example. Although this appears to introduce a substantial error at one step in the calculations, the consistent use of the theoretical value in such cases is found to have very little effect upon the calculated cost per customer. The errors involved are to some extent offsetting, since some overstatement of q for the secondary will result in a corresponding understatement of q' for the primary branches, etc. For this reason, it is thought that the advantages of disregarding such practical discontinuities should not lead to significant error in appraisals of general trends.

Figs. 7 through 10 have been prepared accordingly, to illustrate certain general trends which will accompany moderate deviations from the particular conditions assumed in the illustrative example. It will be noted that the costs given represent only the installed costs of the secondary circuit and primary branches, for the reasons given. In the preparation of these figures it was found convenient to use the general relations of Table III, which do not require separately identifying intermediate steps in the calculations. These relationships are further simplified by dealing in terms of the equivalent number of customers and the equivalent load density per square mile. By substitution of the respective secondary and primary voltages and unit costs of the illustrative example, in the general equations of Table III, it will be found that they reduce to the correspondingly less general relationships of Table IV, which apply specifically to the conditions summarized in Figs. 7 through 10.

It will be noted that Tables III and IV include expressions of the primary circuit transformer cost which was not evaluated or included in the illustrative example, or in Figs. 7 through 10. The principal effect of this omission is to make the cost per customer at unity pf appear to be slightly, but not significantly, higher than at 0.95 pf.

The principal advantage of improved pf

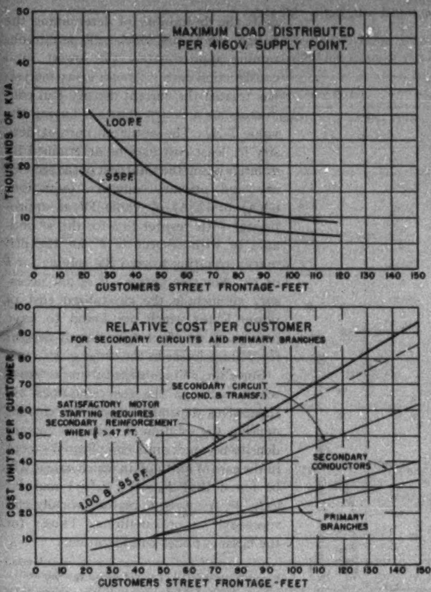

Fig. 9. Illustrative effect in new construction of customers' street frontage on aerial circuit capacity and cost for 1 kva per 120/240-volt customer, with 50-by-100-foot lots, 10^{-3} amperes per 3.3% voltage loss in secondaries, 4.2% in primaries, and 2.5% in transformers

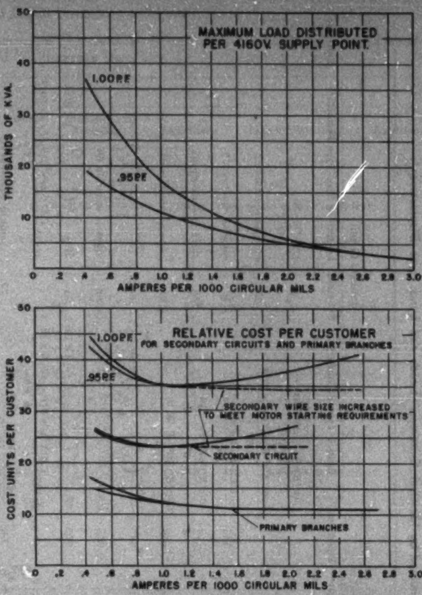

Fig. 10. Illustrative effect in new construction of current density upon aerial circuit capacity and cost for 1 kva per 120/240-volt customer on 50-by-100-foot lots, 3.3% voltage loss in secondaries, 2.5% in transformers, and 4.2% in primaries

is that of reducing the kva load per customer. The subordinate effect upon increasing the maximum load distributed per circuit is of little practical consequence at the primary circuit loads involved in this illustration.

The criteria for satisfying the motor starting limitations, and for determining the relative cost of branch-type versus lateral-type secondaries, are also included in Tables III and IV. If the load density β is not sufficiently high to require a design which is adequate for motor starting, the circuit must be reinforced by providing larger conductors and, in some cases, by designing also for some higher load density.

Variations in nominal secondary supply voltage, Fig. 7, are seen to have very little effect upon relative cost for secondary circuits and primary branches, being essentially constant for all voltages in the range from 110 to 125. A constant ratio of transformation between secondary and primary voltages was assumed.

Permissible voltage loss, in the order of 3%, Fig. 8, is seen to develop approximately the lowest cost per customer. For the primary branches this figure also shows a slight upward trend of cost per customer with increasing circuit load, because of the inherently larger average conductor size needed. The upward trend of average conductor size with circuit load operates to offset the substation economies in such a way that, in some situations, cost considerations may limit practical circuits to sizes considerably smaller than would be permitted by voltage loss limitations alone. For instance, the 4.2% voltage loss of the illustrative example would permit using 4,160-volt primary circuits, or bus-regulated unit substations, as large as 10,000 kva at 0.95 pf, which are substantially greater than has been common practice at this load density of approximately 4,000 kva per square mile.

As the customer's street frontage increases, it is seen (Fig. 9) that the cost per customer for secondary circuits and primary branches increases with an almost linear relationship, and the maximum load per primary circuit decreases as would be expected, with the accompanying decrease in load density. Load density, of course, increases inversely with the customer's land occupancy, and directly with his load.

The relative effect of current density upon aerial circuit capacity and cost is illustrated in Fig. 10, from which it is apparent that the assumed density of 1 ampere per 1,000 CM gives approximately the lowest total cost for the secondary circuit, but that a somewhat higher density will permit approximately one cost unit per customer lower cost for the primary-branch component of the primary circuit.

In Figs. 9 and 10 there is also a suggestion that reinforcement of secondary circuits, as necessary to accommodate 120-volt motor starting, need not increase the total cost per customer in new construction at load densities above 3/4 kva per customer, or 3 kva per 100 street feet.

Inference from Fig. 10, that primary branches should perhaps operate at higher current densities than secondaries, sug-

* A lateral-type secondary circuit costs less than a branch-type when $\left[\frac{0.6a_t\delta^2}{vEF_pF_r}+\left(\frac{Nac}{F_p}+\frac{N'ac'}{F_r}\right)\right]>\left[\frac{1}{s}\left(\frac{0.5a_t\delta}{F_p}+\frac{vEN'ac'}{1.2}\right)\right]$ (78)

* A spot-type secondary costs less than a lateral-type under conditions readily recognized by comparing the sum of equations 70 and 74 with equation 74S.

gests the desirability of determining the design conditions which will permit obtaining approximately the lowest total construction cost. The previous analysis has treated the current density δ in conductors, as a design constant having the value I/A. The optimum current density for least cost may be determined by differentiating the total cost of the secondary and primary circuits (equations 69(A) to 75(A) of Table IV as appropriate) with respect to δ for the secondary, or with respect to δ' for the primary; equating to zero the solving for δ or δ'. For this purpose it is not necessary to include the capitalized cost of power losses which are found to have practically no effect upon circuit designs for voltage losses in the order of 3%.

Since the voltage adjustment factors F which occur in the cost equations are themselves dependent upon the current density, the solution of optimum current density becomes quite complicated except in the case of unity pf, in which case it will be found that $F_p=F_r=F_p''=1$ and F_r' may be expressed mathematically by successive approximations. Thus, for the circuits under consideration.

δ–optimum $=0.177\sqrt[3]{v^3\beta}$ amperes per 1,000 CM for branch-type secondary (79)

δ–optimum $=0.041\sqrt[3]{v^3\beta s}$ amperes per 1,000 CM for a lateral-type secondary (80)

δ'–optimum $=0.34\sqrt[4]{v'^3}\beta$ amperes per 1,000 CM for the primary (81)

Equation 81 is based on the assumption that the unit costs of the transformers and accessories supplying the primary circuits are $a_t'=10{,}000$ cost units and $b_t'=3.5$ cost units per kva.

By reference to Fig. 10 it is seen that the secondary- and primary-branch components of the cost curves are relatively flat at points near their minimum values. Also, in Figs. 7 through 10, it is seen that the cost per kva is practically independent of pf in the range from 0.95 to 1.00. It is therefore concluded that the current density producing the lowest construction cost at unity pf approximately represents the conditions permitting the least cost for all pf in the range from 0.9 to 1.00. It is thought possible that further investigation might indicate this assumption to be valid also at even lower pf.

In Fig. 11, the over-all effect of customers' load upon cost per customer is seen to be a practically linear relationship at constant current density. The relationship is also seen to be almost linear in Fig. 12, for the theoretically ideal condi-

tions which permit the least total construction cost for secondary circuits and primary branches.

The average conductor sizes indicated in Fig. 12 are considerably smaller than had been expected. Therefore, it seems appropriate to review a few considerations which account in part at least for the small wire sizes developed in these illustrative calculations:

1. It will be recalled that the illustrative example included no special provisions for emergency breakdown service, such as is usually provided in cases when failure of supply to one circuit requires redistribution of its load between adjacent circuits. The permissible voltage loss in the thus temporarily enlarged circuits is considerably greater under such emergency conditions, but it seems quite probable that some additional conductor capacity, and therefore a larger average size, might be required.

2. The mechanical strength required to withstand standard wind and ice loading of the conductors, frequently establishes a minimum practical conductor strength which would require a larger copper conductor than needed to satisfy only the electrical characteristics of the circuit. Where cost and other related considerations are favorable, however, there has been a considerable use of steel-reinforced aluminum cable, copperweld, or other high-strength conductor, to provide the required mechanical strength without necessarily providing excess conductivity.

3. The consistent year-to-year growth of customers' loads requires such frequent circuit reinforcement that it is generally good practice to install somewhat larger conductors than would be sufficient for the particular loads at the time when reinforcement becomes necessary.

4. The illustration assumes complete new construction under ideal conditions such as are seldom encountered in practice.

The effect of customer's load upon distribution circuit size, also shown in Figs. 11 and 12, is of considerable interest, since it will be noted that the load limit per circuit at 0.95 pf is in each case approximately proportional to the square root of the load per customer. For several years, this particular relationship between circuit load and load density has been observed by the Philadelphia Electric Company as an empirical characteristic of its secondary-, primary-, and high-tension circuit loads.

It now seems appropriate to examine briefly the effect of current density upon the load distributing capacity of primary-branch circuits. This is shown in Fig. 13 for several values of current density as a function of load density at 0.95% pf. From a review of this figure it will be seen that the square-root relationship is approximately representative of a current density in the order of 1 ampere per 1,000 CM. With the current density adjusted for least cost, a 0.43 power relationship is obtained. The latter relationship is thought to be practically unattainable in a growing system where each new load is almost invariably accommodated by a comparatively "piecemeal" reinforcement of the existing facilities, in such a way as to provide the added capacity for the least practical additional cost.

Diverse Effects of the Community

According to the previously outlined plan, all preceding steps in this analysis have dealt exclusively with the singular effects of individual customers. Having established a method by which these singular effects may be appraised, it is now appropriate to consider the diverse community effects involved in the distribution of power to diverse customers, under diverse conditions which are unquestionably beyond the control of any single customer.

A given customer has exclusive control over the magnitude and time of his maximum demand. The almost obvious corollary is that he can have no control whatever over the corresponding actions of his neighbor, who is supplied from the same circuit. Yet, their joint use of a

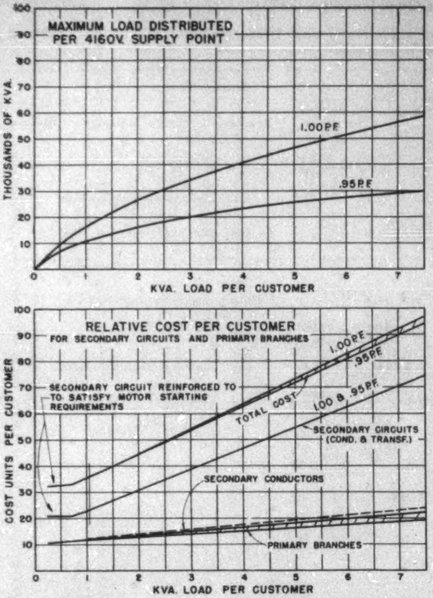

Fig. 11. Illustrative effect in new construction of load per customer on aerial circuit capacity and cost for 120/240-volt customers having 50-by-100-foot lots, with 10^{-3} amperes per CM, 3.3% voltage loss in secondaries, 4.2% in primaries, and 2.5% in transformers

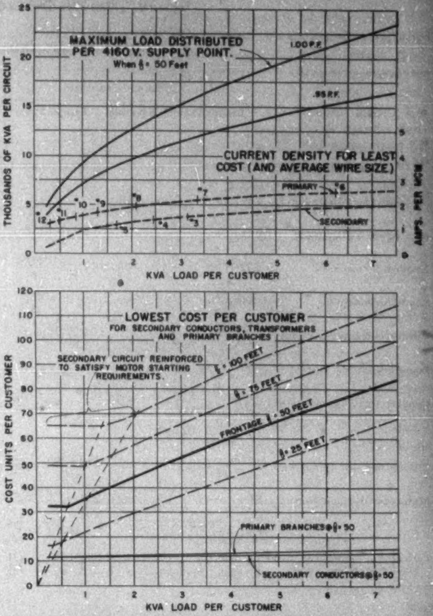

Fig. 12. Illustrative effect in new construction of designs for aerial circuits with lowest cost at 0.95 to 1.00 pf for 120/240-volt customers having lots 100 feet deep with current density adjusted to lowest cost, 3.3% voltage loss in secondaries, 2.5% in transformers, and 4.2% in primaries

common distribution circuit has certain effects to which they jointly contribute.

There was a time, in the days of 1,000-watt flat-irons and 40-watt light bulbs, when the maximum demands of neighboring residential customers were far more nearly uniform than now. With the advent of electric ranges, domestic water heaters, clothes driers and unit air conditioners, however, the loads of residential customers are becoming quite as diverse as the loads of other classes of customers supplied from the same or comparable circuits. Accordingly, it is thought that the only practical way of avoiding possible error in accounting for the diverse load characteristics of customers is to postulate the premise that no distribution circuit will serve two customers having equal or coincident load characteristics. Load diversity, however, is only one of all the community effects which must be accounted for and it should affect only the load component of distribution circuit costs.

On the other hand, random diversity of street layouts, parks, play grounds, cemeteries, rivers, railroads, airports, as well as diverse rights-of-way conditions as affected by rock, trees, and other construction handicaps, including the occasional need for expensive underground construction, are characteristics of the community which are not related to load but have substantial effects upon construction costs. Such diversities are usually subject to objective evaluation only to the extent that their composite effect can be identified by analysis of the distribution plant records for the respective accounts involved. These often-overlooked diversities can have very extensive effects upon costs, perhaps sufficient at times almost to smother the effects of load diversity.

It is therefore apparent that an accounting for the diverse effects of the community requires dealing with them in terms of two general classifications, load diversity and other diversities. Although "other diversities" directly affect the fixed components of unit costs, it will be seen that they also affect the load component of distribution circuit costs to the extent that the numbers of units increase with increasing load density.

Allocation of Construction Costs Between Diverse Loads Supplied from Given Distribution Circuit

By the method developed, it is possible to calculate both the fixed component and the load component of distribution circuit construction cost for each customer served, in terms of kva maximum demand at his meter, his land occupancy, and representative unit costs for the predominantly characteristic type of distribution circuit construction. The representative unit costs are usually obtainable from the property records for each of the particular plant accounts involved, particularly if trended to some consistent construction cost level. In such cost allocations, so long as distribution circuit sizes increase in proportion to the square

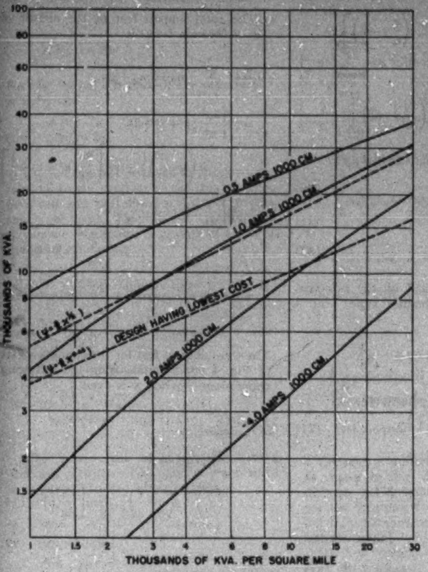

Fig. 13. Illustrative effect in new construction of load density on aerial circuit capacity for various current densities at 0.95 pf for 120/240-volt customers having 50-by-100-foot lots, 3.3% voltage loss in secondaries, 2.5% in transformers, and 4.2% in primaries

root of the load density, it is practical to assume, for copper conductors, a current density of $\delta=1$ ampere per 1,000 CM. The sum of the respective calculated fixed components and load components of construction costs for all of the customers involved will then represent the circuit which these customers would in general require if there were no diversities.

The general noncoincidence of customers' maximum demands is usually accounted for in terms of coincidence factor,[1] having values which range from zero to unity, increasing statistically with increasing load factor and to some extent inversely with the number of similar loads on the circuit. Possible questions concerning whether such factors apply accurately to circuits supplying random combinations of dissimilar loads are not properly a part of the present investigation. It is sufficient to note that the applicable load coincidence factor for any circuit will be the ratio of the maximum demand on the circuit to the sum of the customer's individual maximum demands. Since this ratio will have some value which is less than unity, it follows that the corresponding equivalent load density will also be less. The consequent effect upon calculations made according to the relationship summarized in Tables III and IV may therefore be observed by substituting the correspondingly adjusted value of load density which equals the product of β by the particular coincidence factor found applicable to the circuit in question.

The effect of load diversity upon the calculated construction cost for each of the customers on the circuit may be accounted for by proportionally reducing his load component of costs to account for the applicable coincidence factor for the circuit serving him. The sum of the calculated fixed components and the adjusted load components of construction costs for all customers served by the circuit will then be the total cost corresponding to the predominately characteristic type of distribution circuit construction, if there are no other diversities. The other diversities may then be accounted for with very little likelihood of introducing any significant inequity, by adjusting the total construction cost for each customer by the ratio of the actual cost of the circuit to the cost which has been found to represent the predominately characteristic type of distribution circuit construction.

Considerable additional investigation beyond the immediate scope of this analysis would be required to determine whether the foregoing procedure for distribution circuit cost allocation is more desirable than methods currently followed. It may, however, have some value as a basis for confirming or improving such methods.

Conclusions

1. Dealing with the distribution circuit consistently as a functional entity, and in terms of its natural parameters, has promise of becoming an extremely effective aid to judgment in certain general problems relating to distribution system design and cost allocation.

2. While the example chosen to illustrate this method of analysis must be recognized as having limited general application, the analysis does suggest that little reduction in cost per customer may be expected to accompany any "inching upward" of the secondary voltage level within the range of 115 to 125 volts.

3. Secondaries designed for the supply of load densities less than 4 kva per 100 street feet (1 kva per customer having a 50-foot frontage) must be reinforced to prevent excessive motor-starting voltage dips. It is apparently possible, however, to provide needed reinforcement (Fig. 10) without noticeably affecting the trend of cost per customer until (Fig. 12) the load density reaches about two-thirds of that at which reinforcement becomes necessary.

4. The per customer cost for secondary circuits and primary branches increases almost linearly with the customer's maximum demand and with his street frontage. In designs for least cost, as in Fig. 12, it will be noted that transformers almost entirely account for the load component of secondary-circuit and primary-branch costs per customer.

5. For the case illustrated in Fig. 12, the least cost is within 5% of 65 cost units per 100 feet for all loads up to 4/3 kva per 100 feet of the customer's street frontage plus 7.5 cost units for each additional kva of his load.

6. The empirically observed trend of load per circuit with the square-root of the load density is shown by this analysis to be generally characteristic of circuits having average current densities in the order of 1 ampere per 1,000 CM of copper conductor.

7. Economy favors permitting current density to exceed 1 ampere per 1,000 CM where practical in aerial circuit designs.

8. The curves of maximum load distributed per 4,160-volt supply point in Fig. 12, suggest that bus-regulated substations might be found to be practical in unit sizes substantially larger than has been general practice. At 1 kva per customer, which represents approximately 4,000 kva of circuit load per square mile in this illustration, it is theoretically possible to distribute as much as 7,000 kva from such a unit substation at 0.95% pf.

9. Analyses of trends in distribution plant costs might become substantially more informative if organized so as to distinguish separately between the factors which affect the fixed component and those which affect the load component of construction costs.

Appendix I. Derivation of Equations for Equivalent Circuits of Figs. 3 and 4

Referring to Figs. 3 (branch type) and 4, let y indicate the number of a lateral counting from the extremity of a riser branch. The number of unit loads picked up by a lateral is

$$q_y=\left(\frac{2}{f}y\frac{q}{n}f+1\right)-2+2\times\frac{1}{2}=\frac{2q}{n}y(y>0<n)$$

$$q_0=\frac{1}{4}\qquad (y=0)\qquad (82)$$

$$q_p=(2q+1)-2+2\times\frac{1}{4}=2q-\frac{1}{2}\qquad (y=n)$$

The total number of unit loads picked up is therefore

$$Q=2\left(q_0+\sum_{y=1}^{y=n-1}q_y\right)+q_p$$

$$=2\left\{\frac{1}{4}+\frac{2q}{n}[1+2+3\ldots(n-1)]\right\}+2q-\frac{1}{2}$$

$$=2qn\qquad (17)$$

since

$$1+2+3\ldots x=\frac{x(x+1)}{2}\qquad (83)$$

For the lateral type circuit shown in Fig. 3

$$Q=(2q+1)-2+2\times\frac{1}{2}=2q\qquad (17)$$

The half-length of each lateral is

$$d_y=y\frac{q}{n}f\text{ feet}\qquad (84)$$

and for the principal lateral

$$d_p=qf\text{ feet }(y=n)\qquad (18)$$

The half-length of a riser branch is

$$d_r=ns\qquad (19)$$

Therefore the total circuit length is

$$D=4\sum_{y=0}^{y=n-1}d_y+2d_p+2d_r$$

$$=\frac{4q}{n}f\,[1+2+3\ldots(n-1)]+2qf+2ns$$

$$=Q\left(f+\frac{s}{q}\right)\qquad (n>0)$$

$$Qf\qquad (n=0)\qquad (20)$$

The ampere-feet in half of each lateral of Fig. 3 (branch type) and in half of each even-numbered lateral of Fig. 4 is

$$m_y=if\left\{\left[1+2+3\ldots\left(\frac{q}{n}y-1\right)\right]+\frac{1}{2}\frac{q}{n}\right\}$$

$$=if\left(\frac{q}{n}y\right)^2\text{ ampere-feet }(y<n)\qquad (85)$$

For the odd-numbered laterals shown in Fig. 4

$$m_y=if\left\{\left[\frac{1}{2}+1\frac{1}{2}+2\frac{1}{2}\ldots\left(\frac{q}{n}y-1\right)\right]+\frac{1}{2}\frac{q}{n}y\right\}$$

$$=if\left\{\frac{1}{2}\left[1+3+5\ldots\left(\frac{2q}{n}y-2\right)\right]+\frac{1}{2}\frac{q}{n}y\right\}$$

$$=\frac{if}{2}\left[\left(\frac{q}{n}y\right)^2+\frac{1}{4}\right]\text{ ampere-feet }(y<n)\qquad (86)$$

since

$$1+3+5\ldots x=\frac{(x+1)^2}{4}\qquad (87)$$

The ampere-feet in half of the principal lateral in Figs. 3 (branch type) and 4 (n is even) is

$$m_p=if\left\{[1+2+3\ldots(q-1)]+\frac{1}{4}q\right\}$$

$$=\frac{if}{2}q\left(q-\frac{1}{2}\right)=q^2\frac{if}{2}\text{ approximately ampere-feet}\qquad (21)$$

and in Fig. 4 (n is odd) is

$$m_p=if\left\{\frac{1}{2}[1+3+5\ldots(2q-2)]+\frac{1}{4}q\right\}$$

$$=\frac{if}{2}\left[q\left(q-\frac{1}{2}\right)+\frac{1}{4}\right]=q^2\frac{if}{2}\text{ approximately ampere-feet}\qquad (21)$$

The ampere-feet in half of the lateral of Fig. 3 (lateral type) is

$$m_p=if\left\{[1+2+3\ldots(q-1)]+\frac{1}{2}q\right\}$$

$$=q^2\frac{if}{2}\text{ ampere-feet}\qquad (21)$$

The ampere-feet in a section of the riser branch between any y and $Y+1$ numbered lateral is

$$\Delta m_r=is\left(\frac{1}{4}+\sum_{y=1}^{y=y}q_y\right)$$

$$=is\left[\frac{1}{4}+\frac{2q}{n}(1+2+3\ldots y)\right]$$

$$=is\left[\frac{q}{n}y(y+1)+\frac{1}{4}\right]\text{ ampere-feet}\qquad (88)$$

The ampere-feet in half a riser branch is therefore

$$m_r=\sum_{y=0}^{y=n-1}\Delta m_r$$

$$=is\left\{\frac{q}{n}[1^2+2^2+3^2\ldots(n-1)^2]+\frac{q}{n}[1+2+3\ldots(n-1)]+\frac{n}{4}\right\}$$

$$=isn\left[\frac{q}{3n}(n^2-1)+\frac{1}{4}\right]=n^2\frac{isq}{3}\text{ approximately ampere-feet}\qquad (22)$$

since

$$1^2+2^2+3^2\ldots x^2=\frac{x(x+1)(2x+1)}{6}\qquad (89)$$

The total ampere-feet of the circuit of Fig. 3 (branch type) is

$$M=4\sum_{y=0}^{y=n-1}m_y+2m_p+2m_r$$

$$=if\left\{\frac{2q^2}{n^2}[1^2+2^2+3^2\ldots(n-1)^2]+q\left(q-\frac{1}{2}\right)\right\}+isn\left[\frac{2q}{3n}(n^2-1)+\frac{1}{2}\right]$$

$$=ifq\left[\frac{q}{3n}(2n^2+1)-\frac{1}{2}\right]+isn\left[\frac{q}{3n}(2n^2-2)+\frac{1}{2}\right]$$

$$=\frac{Qi}{3}(qf+ns)\text{ approximately ampere-feet}\qquad (23)$$

The total ampere-feet for the configurations of Fig. 4 are obtained from the following expressions. When n is even

$$M=if\left\{\frac{2q^2}{n^2}[2^2+4^2+6^2\ldots(n-2)^2]+\frac{2q^2}{n^2}[1^2+3^2+5^2\ldots(n-1)^2]+\frac{1}{2}\left(\frac{n}{2}\right)+q\left(q-\frac{1}{2}\right)\right\}+isn\left[\frac{2q}{3n}(n^2-1)+\frac{1}{2}\right]\text{ ampere-feet}\qquad (90)$$

and when n is odd

$$M=if\left\{\frac{2q^2}{n^2}[2^2+4^2+6^2\ldots(n-1)^2]+\frac{2q^2}{n^2}[1^2+3^2+5^2\ldots(n-2)^2]+\frac{1}{2}\left(\frac{n-1}{2}\right)+q\left(q-\frac{1}{2}\right)+\frac{1}{4}\right\}+isn\left[\frac{2q}{3n}(n^2-1)+\frac{1}{2}\right]\text{ ampere feet}\qquad (91)$$

These equations are equal to

$$M=if\left\{\frac{2q^2}{n^2}[1^2+2^2+3^2\ldots(n-1)^2]+q\left(q-\frac{1}{2}\right)+\frac{n}{4}\right\}+isn\left[\frac{2q}{3n}(n^2-1)+\frac{1}{2}\right]$$

$$=if\left\{q\left[\frac{q}{3n}(2n^2+1)-\frac{1}{2}\right]+\frac{n}{4}\right\}+isn\left[\frac{q}{3n}(2n^2-2)+\frac{1}{2}\right]$$

$$=\frac{Qi}{3}(qf+ns)\text{ approximately ampere-feet}\qquad (23)$$

For the lateral-type circuit of Fig. 3

$$M=2m_p=\frac{Qi}{2}qf\text{ ampere-feet}\qquad (23)$$

It should be noted that the foregoing expressions for Q, m, and M also may be derived on the assumption of a uniformly distributed load throughout the area. It will be apparent that the load density is $1/fs$ unit loads per square foot and since the area of the diamond-shaped area served by a branch-type equivalent circuit is 2 $qfns$

$$Q=\frac{1}{fs}\times 2qfns=2qn \qquad (17)$$

For the lateral-type circuit the area served is $2qfs$, and

$$Q=\frac{1}{fs}\times 2qfs=2q \qquad (17)$$

The ampere-feet involved in any instance is equal to the product of the total current involved and the effective distance to the center of load, which is the rectangular distance to the center of gravity of the area involved

$$m_p=\frac{2qi}{2}\times\frac{qf}{2}=q^2\frac{if}{2}\text{ ampere-feet} \qquad (21)$$

$$m_r=\frac{2qni}{2}\times\frac{1}{3}ns=n^2\frac{isq}{3}\text{ ampere-feet} \qquad (22)$$

and for the branch-type circuit

$$M=4\times\frac{Qi}{4}\times\frac{qf+ns}{3}=\frac{Qi}{3}(qf+ns)\text{ ampere-feet} \qquad (23)$$

The power loss in a system having uniform conductor size may be determined as follows. In half of each lateral

$$p_y=i^2fR\left(\frac{1^2}{2}+\frac{3^2}{2}+\frac{5^2}{2}\ldots\frac{qy}{n}\text{ terms}\right)$$
$$=\frac{i^2fR}{3}q\frac{y}{n}\left[\frac{qy^2}{n}-\frac{1}{4}\right]\text{ watts per conductor} \qquad (92)$$

since

$$1^2+3^2+5^2\ldots x\text{ terms}=\frac{1}{3}\times(4x^2-1) \qquad (93)$$

The power loss in a section of the riser branch between any y and $y+1$ numbered lateral is from equation

$$\Delta p_r=i^2sRq^2\frac{y^2}{n^2}(y^2+2y+1)\text{ watts per conductor} \qquad (94)$$

The power loss in a riser branch is therefore

$$p_r=\sum_{y=0}^{y=n-1}\Delta p_r=i^2\frac{sRq^2}{n^2}\times\left[\begin{array}{l}1^4+2^4+3^4\ldots(n-1)^4+\\2\{1^3+2^3+3^3\ldots(n-1)^3\}+\\1^2+2^2+3^2\ldots(n-1)^2\end{array}\right]$$
$$=i^2sRq^2\left(\frac{n^3}{5}-\frac{n}{3}+\frac{1}{7.5n}\right)=\frac{i^2sRq^2n^3}{5}\text{ approximately} \qquad (95)$$

since

$$1^4+2^4+3^4\ldots x^4=\frac{1}{30}\times(x+1)(2x+1)\times(3x^2+3x-1) \qquad (96)$$

and

$$1^3+2^3+3^3\ldots x^3=\frac{x^2(x+1)^2}{4} \qquad (97)$$

The total power loss in a branch type circuit is therefore

$$P=4\sum_{y=0}^{y=n-1}p_y+2p_p+2_{pr}$$
$$=\frac{i^2fR}{3}\left[\frac{4q^3}{n^3}\{1^3+2^3+3^3\ldots(n-1)^3\}-\frac{q}{n}\{1+2+3\ldots(n-1)\}+2q^3-\frac{q}{2}\right]+$$
$$\frac{2}{5}i^2sRq^2n^3=Qi^2Rq\left(\frac{qf}{6}+\frac{2n^2s}{5}\right)\text{ approximately} \qquad (25)$$

For a lateral-type circuit

$$P=2p_p=\frac{2}{3}i^2fR_q\left(q^2-\frac{1}{4}\right)=Qi^2\frac{Rq^2f}{3}\text{ approximately} \qquad (25)$$

Appendix II. Derivation of Equations for Radial Circuit of Fig. 5

Consider a uniform system of unit loads as shown in Fig. 5 where the horizontal distance between loads is f feet and the vertical distance is s feet. Each load is fed from the source of supply by an individual feeder which reaches the load through a vertical path and a horizontal path as indicated. The area which may be thus served with a maximum voltage loss will be diamond-shaped as shown, and the height and width of the diamond will be theoretically equal. If a larger area is to be symmetrically served by a number of such systems, it is apparent that the corners of each diamond-shaped area will be midway between individual pickup points horizontally or vertically. Thus, if the parameters of the area served are indicated as qf and ns as before, it will be evident that qf must be a multiple of $f/2$. Since the pickup points at the vertical corners of the diamond are spaced $2s$ apart for the staggered spacing of pickup points shown in Fig. 5, and which will be obtained for systems of the higher voltage levels, it is apparent that n must be an integer.

It will be apparent also from Fig. 5 that there is a possibility of a pickup point falling on the boundary. Hence, for purposes of calculating the maximum voltage loss, we may interpret d_p as being the maximum horizontal distance and d_r as the maximum vertical distance from the supply point in the area served. Therefore

$$d_p=qf\text{ feet} \qquad (18)$$

$$d_r=ns\text{ feet} \qquad (19)$$

$$m_p=iqf\text{ ampere-feet} \qquad (21)$$

$$m_r=ins\text{ ampere-feet} \qquad (22)$$

The remainder of the parameters are most readily obtained by considering the system as one having a uniformly distributed load throughout the area. As indicated in Appendix I, therefore, the values of Q and M will be the same as therein derived. Since each unit load is supplied by a separate feeder

$$D=\frac{M}{i}=\frac{Q}{3}(qf+ns)\text{ feet} \qquad (20)$$

and

$$P=\frac{Qi^2R}{3}(qf+ns)\text{ watts per conductor} \qquad (25)$$

Appendix III. Development of Voltage Adjustment Factor F

Let E_1 represent the phase-to-neutral voltage at the nearest customer, V_t the component of line drop in phase with the current, and V_q the quadrature component of line drop. The magnitude of the phase-to-neutral voltage at the last customer is given by the expression

$$E_2=\sqrt{(E_1+V_t\cos\theta+V_q\sin\theta)^2+(V_q\cos\theta-V_t\sin\theta)^2}\text{ in volts} \qquad (98)$$

and the permissible difference in magnitude between E_2 and E_1 is

$$E_2-E_1=\frac{vE}{100}\text{ volts} \qquad (99)$$

Since from equations 9 or 11

$$\frac{vE}{100}=\frac{Kd}{F},\text{ or }\frac{mR}{F}=\frac{V_t}{F}\text{ volts} \qquad (100)$$

from equations 98 through 100 the following relationship is obtained

$$\frac{1}{F}+\frac{E_1}{V_t}=\sqrt{\left(\frac{E_1}{V_t}\right)^2+2\frac{E_1}{V_t}\cos\theta+\frac{V_q}{V_t}\times\sin\theta+1+\left(\frac{V_q}{V_t}\right)^2} \qquad (101)$$

Solving equation 101 for V_q/V_t the following is obtained

$$\frac{V_q}{V_t}=\frac{E_1}{V_t}\left[\sqrt{\sin^2\theta+\left(\frac{V_t}{E_1}\right)^2\left(\frac{1}{F^2}-1\right)-\frac{2V_t}{E_1}\left(\cos\theta-\frac{1}{F}\right)}-\sin\theta\right] \qquad (102)$$

If $E_1=E(1-1/2\,v/100)$, from equation 100

$$\frac{E_1}{V_t}=\frac{1}{F}\left(\frac{100}{v}-\frac{1}{2}\right)=\frac{100}{Fv}\text{ approximately} \qquad (103)$$

If equation 103 is substituted in equation 102 and if it is recognized that $V_q/V_t=\tan\alpha$, where α is the effective phase angle of the circuit, the following expression results

$$\tan\alpha=\frac{100}{Fv}\left[\sqrt{\sin^2\theta+\frac{v^2}{10^4}(1-F^2)+\frac{v}{50}(1-F\cos\theta)}-\sin\theta\right] \qquad (104)$$

For $\theta=0$ (unity pf) equation 104 reduces to

$$\tan\alpha = \frac{1}{F}\sqrt{(1-F)\left(1+F+\frac{200}{v}\right)}$$

$$= \frac{14.3}{F}\sqrt{\frac{1-F}{v}} \text{ approximately} \qquad \textbf{(105)}$$

The solution of equations 104 and 105 for F at various pf in terms of $\tan \alpha$ and $(\tan \alpha)/F$ is given in Fig. 1. To eliminate a fourth variable, v has been taken at a nominal value of 3.75%. Moderate variations in v from this value will have a negligible effect except in the case of unity pf, for which Fig. 1 also becomes applicable, provided the abscissas are multiplied by the ratio $\sqrt{v/3.75}$.

◆

Discussion

Constantine W. Bary (Philadelphia Electric Company, Philadelphia, Pa.): I would like to commend Mr. Kidder and Mr. Neher on their well-conceived, well-formulated and valuable paper. It is a milestone in the study of the parameters affecting the economics of power distribution systems. I was especially interested in the authors' conclusions relating to the basic concepts of a modern power distribution system and their mathematical rationalization of its cost behavior depicted in Figs. 11 and 12, as applying to the functional elements of primary branches, secondary transformers, and secondary circuits.

As a result of work done by Mr. Kidder and his associates in the Philadelphia Electric Company over 20 years ago, we have been using in our cost-of-service analyses the concepts and major parameters of power systems distribution cost behavior now so ably described in the present paper. There is no question in my mind that such concepts as the functional components of the power distribution system and such major parameters as the number of customers and their maximum demands form the cornerstones for a comprehensive structure of determining the cost behavior of a power distribution system, but there are two points which should be kept in mind by those who have occasion to build on the foundation laid by this paper:

1. It must be appreciated that the very considerable amount of load diversity which we have come to associate with supplying the usual number of residential customers per circuit diminishes quite rapidly as the number becomes less than 20 and vanishes at one customer per circuit. The relationship is one to which I have previously referred as the "first law of load diversity".[1]

2. In actual practice there is some fixed maximum size of load that can be carried at a given tap-off point, limited by the practical size of a distribution transformer installation—a fact which should be expected to introduce a point of discontinuity in the cost curves and will increase the cost per customer materially at noncoincident maximum demands beyond the range considered by the authors.

To illustrate the effect of load diversity on distribution transformer loading, let us consider a group of residential customers having equal noncoincident maximum demands of 3.5 kva per customer. According to curve D of Fig. 1 of reference 1 of the paper, the corresponding average load per customer in terms of transformer maximum demand (sometimes referred to as diversified maximum demand) would be 2.4 kva per customer in groups of 2 customers per circuit; 1.9 kva per customer in groups of 4 per circuit; 1.6 kva per customer in groups of 10 per circuit; 1.5 kva per customer in groups of 20 per circuit, and 1.4 kva per customer in groups of 25 customers per circuit. In this case, therefore, the transformer load per customer might range anywhere from 1.4 to 3.5 kva, depending only upon the number of customers served under the circumstances.

For the range of customers' loads considered by the authors, I think that the numbers of customers per transformer probably are sufficiently large so that the single parameter for the "load" or the "maximum demand" used by them in plotting the cost curves depicts the relationships within that range without risk of introducing appreciable error. Beyond 7.5 kva per customer, however, it certainly becomes essential to recognize the increasingly important trend of load diversity with the decreasing number of customers per transformer. As the maximum demands of residential customers continue to increase to levels above 7.5 kva per customer, I am inclined to believe that an adequate appraisal of the effect upon cost per customer will require dealing with two "load" parameters: one dependent upon the customers' noncoincident maximum demands above some predetermined value, and another dependent on their diversified maximum demand.

It will be noted that the load component of distribution system cost is more closely related to the load per circuit than it is to individual customer's maximum demand at his service entrance, while the fixed or area coverage component of such cost is basically dependent upon the number of customers per tap-off point. Since in actual practice there is some fixed maximum size of load that can be carried at a given tap-off point, the number of customers per tap-off will decrease with an increase in the load size of customers (especially beyond the size of 5, 7, or 10 kva per customer), and such decrease in the number of customers per tap-off point will be accompanied by an increase in the group coincident factors, in accordance with the first law of load diversity, which further diminishes the possible number of customers per tap-off point. The over-all effect of these conditions will be reflected in higher unit cost per customer of the so-called "fixed" or area coverage costs of the tap-off points, and this in turn can be traced back fundamentally to the increase in the customers' load size as measured by their noncoincident maximum demands. In our system of cost analysis, we have been reflecting this condition in the past, on an empirical basis, for customers of the small general light and power class, supplied from the secondary system, which has had for many years back a relatively large number of customers with maximum demands in excess of 5 kva.

Although empirically these conditions may be rationalized on the basis of a 50-kva or a 100-kva secondary transformer installation per tap-off point (as a practical maximum under present-day conditions depending upon local conditions), I hope that the authors will find an opportunity to pursue further their fundamental analyses of the power distribution parameters with a view to establishing a mathematical rationalization of the two load parameters, which appear to be necessary to reflect fully the behavior of power distribution costs for a wide range of customers' load requirements, beyond the 5, 7, or 10 kva per customer. The importance of realizing the existence of these two parameters will be, in my opinion, of ever-increasing significance in the economics of power distribution systems of the future, as the kva maximum demands of residential customers increase by leaps and bounds with the ever-growing use of electricity, and especially as a result of rapidly increasing saturations of residential air conditioning and, in the not too distant future, with the growth of the heat pump and other types of space heating loads, which will place such customers' maximum demands considerably beyond the 5, 7, or 10 kva per customer values, and which will be accompanied with an increase in their group coincidence factors.

REFERENCE

1. Load-Structure of a Modern Electric Utility System, Constantine W. Bary. *Proceedings*, American Power Conference, Chicago, Ill., vol. XVI, 1954, p. 401.

D. N. Reps and **H. E. Lokay** (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The approach taken by the authors to solve a complex problem is a very interesting one. It is our interpretation that the principal purpose of this paper is to present methods for analyzing primary and secondary distribution system costs with the ultimate objective of obtaining maximum economy of system design and operation. The authors have chosen to present results of hypothetical examples showing the relationships of cost per customer versus kva demand per customer.

The relationships established in this paper are quite general, and we note with great interest that a somewhat different approach to distribution system cost evaluation which we have taken leads to results which closely agree with the cost picture presented in Fig. 11. A brief description of the methods employed in our study follows.

The distribution system is designed to serve load of a stipulated kva-per-square-mile load density with costs put on a dollars-per-kva basis. The uniformly distributed load, to be similar to the subject paper, could be subdivided into any desired kva demand for customer, and the total system cost can be visualized on a dollars-per-customer basis. In our analysis, we divide the system into five major components: subtransmission circuits, distribution substations, primary-feeder circuits, distribution transformers, and secondaries and services.

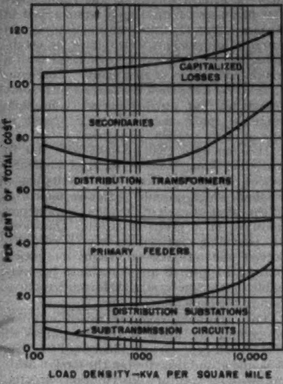

Fig. 14. Typical per-cent cost allocation to each system component and capitalized energy losses for minimum-cost systems at each load density

All the major components were included because every type of system will have a different form that each component will take. For instance, a primary-network system will require dual subtransmission supply to each primary-network distribution substation, and primary feeders will be networked. A radial primary distribution system on the other hand may have dual-transformer and dual-subtransmission-supply distribution substations, or may be a simple radial system throughout. Secondaries may be radial or banked. It will be noted that the form the system components will take determines the "service quality" and "service continuity" rendered by the system as a whole. Having stipulated in advance what these system attributes should be, it is then possible to optimize (minimize) the cost of that type of system to serve a given load density. Two, or several, system arrangements can be studied, if necessary, for purposes of economic comparisons of alternatives.

The variables or parameters entering into such a cost optimizing or minimizing procedure are: subtransmission voltage, distribution-substation size, primary-feeder voltage and the number of primary feeders per substation, distribution transformer size, secondary voltage and secondary conductor size, and pole spacings.

From the studies we have made, a typical per-cent cost allocation to each system component and capitalized energy losses for minimum-cost systems at each load density are shown in Fig. 14. This particular case is for a radial system with a 34.5-kv single subtransmission-circuit supply to single-transformer distribution substations, and radial primary feeders operating at 2,400/4,160 volts. Secondary voltage is 120/240 volts. Since Mr. Kidder and Mr. Neher consider primary circuits, distribution transformers, and secondaries only, in Fig. 15 we have replotted Fig. 14 to show only these components.

Fig. 16 is obtained from Fig. 11. To convert kva per customer to kva per square mile, we have assumed that a load of 1 kva per customer represents a load density of 2,000 kva per square mile. This relationship comes about if 1 square mile is assumed to contain ten streets in both directions, with lots of 50-foot frontage on both sides of the streets in one direction. A load density increase then involves greater demand per customer, since the area at 2,000 kva per square mile is assumed saturated with residences.

The similarity in the per-cent costs allocated to the three components from our analysis, and the authors', is apparent. This close similarity indicates that our approach to system cost determination which considers uniformly distributed load rather than load per customer, and dollars per kva rather than cost per customer, leads to the same results as the authors' analysis.

However, the minimum-cost system for a given load density might, e.g., utilize different conductor sizes and substation ratings than a load density just a relatively small increment greater. Obviously it would not be practicable to change out conductors continually, and replace substation transformers and distribution transformers with different size units to satisfy the optimum requirements for each slightly greater density as the load grows. Hence the most economical system is one which minimizes total investment over some considerable period of time. This procedure would require "overdesigning" some or all of the components at the outset to eliminate the need for costly changeovers at too frequent intervals. Such overdesigning is often mandatory if for no other reason than that ratings of equipment and conductor sizes are standardized at specific values. These considerations apply to both the authors' and our approach to the problem as presented herein.

We are in agreement with the conclusions of Kidder and Mr. Neher. An approach such as theirs to the problem of distribution system cost optimization definitely leads to a better understanding of the subject. Further investigation including the effects of load growth will shed additional light on the problem and prove exceedingly useful in distribution system planning.

A. H. Kidder and J. H. Neher: We are most appreciative of the interest shown in our paper, particularly of the discussions which raised points that deserve careful consideration. Also, one of the reviewers whose name is not known to us raised an additional point which is deserving of recognition.

Mr. Bary's emphasis of the need to

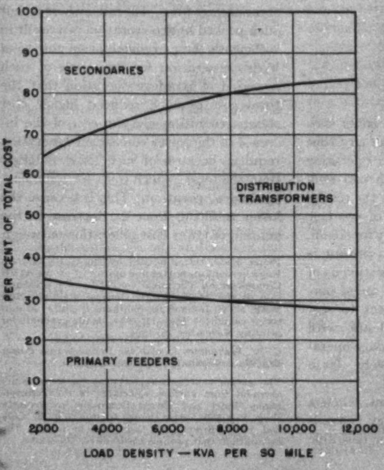

Fig. 15 (left). Fig. 14 replotted to show only primary circuits, distribution transformers, and secondaries

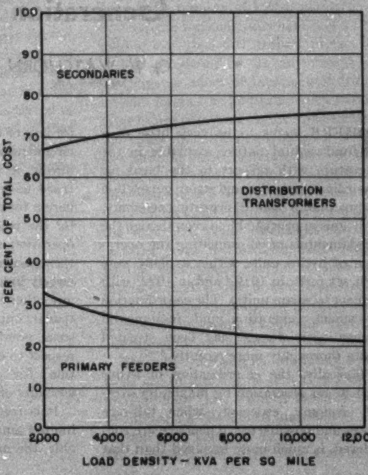

Fig. 16 (right). Fig. 11 replotted converting kva per customer to kva per square mile

recognize the effects of load diversity on distribution transformer loading, as well as the effect of the natural limit on maximum distribution transformer size, is important, and both effects can be accounted for readily by a slight extension of our analysis. If β represents the load density on a fully diversified or coincident load basis, these effects will modify the secondary equations only, and it may be shown that the only appreciable change will occur in equations 73 and 74 for the transformer cost per customer which may be rewritten as

$$\text{Transformer cost per customer} = \frac{a_t}{2Q} + \frac{\gamma \beta b_t}{\phi} \qquad (106)$$

in which $2Q$ is the number of customers per circuit, as given by equation 56 or 57, and γ represents the ratio of the coincidence factor Ω_n for $2Q$ customers to the coincidence factor for an infinitely large number of customers Ω_∞. As shown in reference 1 of the paper

$$\gamma = \frac{\Omega_n}{\Omega_\infty} = 1 + \frac{1-\Omega_\infty}{2Q\Omega_\infty} \qquad (107)$$

If the transformer size is limited to L_{max} in kva

$$2Q \leq \frac{\phi L_{max}}{\gamma \beta}, \text{ number of customers} \qquad (108)$$

In this case $2Q$ should be determined by equation 108 in the range where equation 108 yields lower values of $2Q$ than equations 56 and 57.

It is of considerable interest to know that the independent approach of Mr. Reps and Mr. Lokay develops cost trends quite similar to those which can be derived from information given in the paper. In the present state of the art, however, we think that it is important to emphasize the distinction between cost trends and costs, because it has been our experience that alternate approximate designs of distribution circuits will develop quite similar cost trends, but they may not necessarily develop identical costs in otherwise equal situations.

Although the curves in Figs. 15 and 16 have similar general trends, it will be noted, e.g., that there is considerable difference between their respective slopes as well as the corresponding absolute values represented at nearly all load densities. It is quite probable that these divergencies may be attributed in part to lack of sufficient data.

These observations therefore should not be construed to the discredit of the discussers. They merely emphasize the possibility of pitfalls which unfortunately may befall one who on occasion finds it necessary to deal with approximations. It was for this reason that we undertook to develop a method by which it would be possible to determine the number of given loads which a distribution circuit could supply under given conditions, together with the total load, the circuit length, and total conductor weight required, as necessary in order to estimate its total cost under given conditions.

In this particular case, it is unfortunate that the large number of parameters and the multiplicity of circuits involved in any distribution circuit make it necessary to deal in terms of cost as the only practical common denominator. For this reason it may be helpful to remind the reader that the first part of the paper, summarized in Tables I and II, serves to develop certain essential dimensions which must be established before costs can be evaluated with a maximum degree of confidence. Cost considerations were then introduced with some reluctance, but only as necessary to illustrate the application of the basic theory in one of many possible situations.

It is our hope that we have been able to introduce some measure or rigor in distribution circuit synthesis by developing a method which permits accurate appraisal of the effect of each of the many parameters involved in a given situation. Questions of providing for emergency breakdown service and advance provisions for anticipated load growth are thought to be amenable to solution by straightforward application of the principles outlined.

The unknown reviewer raised a point concerning the loads at the extremities of the branch-type circuit, illustrated in Figs. 2, 3, and 4, and described in the section dealing with elementary distribution circuits. We find that we had failed to point out that the loads shown in these extremities accurately represent the situation only when $qf = ns$, as at unity pf. Rigorous representation of these boundary loads at other pf's is apparently impractical at this stage and should have been acknowledged. The effect of failure to account accurately for this effect would be to overstate somewhat the amount of load which could be distributed by the circuit. The design thus derived can be checked and modified in any situation where it is found necessary to compensate for this neglected circuit reactance effect.

Co-ordination of Hydro and Steam Generation

C. W. WATCHORN
MEMBER AIEE

THERE seems to be very little of a fundamental nature available in the literature with respect to the basis for co-ordinating hydro and steam generation for maximum over-all operating economy.[1–3] This appears to be so even though the fundamentals of co-ordinating the operation of hydro units within a plant were first set forth in 1919,[4] and in 1922[5] with respect to steam units. The co-ordination of steam generation and incremental transmission losses has been treated quite thoroughly more recently.[6–11]

Basically, the co-ordination of hydro and steam generation for maximum overall economy, especially when tail-race losses and possible use of pondage are considered, is much more involved than that for any of the foregoing since, under such circumstances, the operation at any time during a period of pondage operation (used as periods of drawdown and refill herein for convenience) affects the results for the whole of that period of pondage operation, whereas, particularly for steam, the operation from instant to instant is largely independent of the operation as of any other instant. Such facts are of particular importance with respect to seasonal pondage operation, and also with respect to daily or weekly pondage operation for which comparatively large amounts of water are involved.

It is frequently thought that, when a limited amount of hydro energy is available, the most advantageous or desirable operation is to utilize such energy in the peak of the load to as great an extent as possible since such operation results in the smallest amounts of required higher cost steam generation. The fallacy here is that such peaked hydro operation can result in sufficiently large reductions in the total hydro generation for the whole of such a period of pondage operation that the total cost of such reduced higher cost steam generation and the cost of the increase in the lower cost steam generation required because of such losses is larger than the total of such costs for some flatter hydro operation. This is because the losses resulting from the increase in the amount of lower cost generation outweigh

Paper 55-33, recommended by the AIEE System Engineering Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted May 11, 1954; made available for printing November 16, 1954.

C. W. WATCHORN is with the Pennsylvania Power and Water Company, Baltimore, Md.

The author expresses appreciation for the encouragement from various associates in the Pennsylvania Water and Power Company, particularly H. A. Von Eiff. Also thanks are due to R. W. Cole and F. F. Brooks for their care in making the calculations that provide the basis for the study.

the savings resulting from the reduction in the amount of higher cost steam generation required. The optimum operation is a compromise between the operation that results in the maximum amount of hydro generation on the one hand, and the operation that results in the hydro generation that replaces the maximum possible amount of the otherwise higher cost steam generation on the other hand. Such optimum operation, in contrast with this latter operation, results rather in such losses in hydro generation in reducing the amount of higher cost steam generation required that, together with the cost for the resulting increase in the lower cost steam generation, maximum over-all economy is obtained for the whole of the period of operation.

The investigation reported here was started in an attempt to develop or discover a basis for automatically co-ordinating hydro and steam generation. The results were determined experimentally by means of what might appropriately be called a mathematical model of a combined hydro and steam system which could be operated fairly conveniently in any manner desired and for which the results could be measured to any practical degree of precision necessary. This approach was used since it appeared, after much study, that the problem could not readily be solved in any other manner.

Nomenclature

c = cost of the system steam generation, dollars per hour
g_h = generation of the hydro plant, megawatts (mw)
g_s = system steam generation, mw
q = hydro plant discharge, thousand cubic feet per second (mcfs)
r = rate of pond inflow in mcfs at time t in hours
H = head on the hydro plant, feet
I = intake losses, feet
L = system load in mw at time t in hours from the beginning of the operation under consideration
M = tail-race elevation, feet
N = incremental water value, dollars per hour per mcfs. It is a constant during the whole of any period of pondage operation of the hydro plant under consideration (used as drawdown and refill herein for convenience, but not limited thereby)
P = pond elevation at time t, feet
S = withdrawal from storage in mcfs-hours at time t as compared with zero withdrawal for a full pond
T = period of operation, hours
$\frac{dc}{dg_s}$ = system incremental steam cost, dollars per hour per mw
$\frac{dg_h}{dq}$ = incremental hydro equivalent of the hydro plant under consideration, mw per mcfs
$\frac{\partial g_h}{\partial q}$ = incremental hydro equivalent with constant head, mw per mcfs
$\frac{\partial g_h}{\partial H}$ = incremental change in hydro generation with respect to head with constant discharge, mw per foot
$\dot{q}$ = time rate of change of the hydro plant discharge, mcfs per hour
$\dot{r}$ = time rate of change of inflow into the pond of the hydro plant, mcfs per hour
$\frac{dI}{dq}$ = incremental change in the hydro plant intake losses with respect to plant discharge, feet per mcfs
$\dot{L}$ = time rate of change of the system load, mw per hour
$\frac{dM}{dq}$ = incremental change in tail-race elevation with respect to plant discharge, feet per mcfs
$\frac{dP}{dS}$ = incremental change in pond elevation with respect to storage, feet per mcfs-hour
$\ddot{q}$ = first derivative of the time rate of change of the hydro plant discharge, or the second derivative of the hydro plant discharge as a function of time, mcfs per hour^2
$\ddot{L}$ = first derivative of the time rate of change of the system load, or the second derivative of the system load as a function of time, mw per hour^2
$\frac{d^2P}{dS^2}$ = second derivative of the pond elevation as a function of storage, feet per mcfs-hour^2

Results

The investigation indicated that maximum economy may possibly be obtained in the co-ordination of hydro and steam generation when the product of the system incremental steam cost and of the difference between the ratio of the time rate of change of the load to the time rate of change of the hydro plant discharge and the incremental hydro equivalent of the hydro plant under consideration is equal to a constant during the whole period of drawdown and refill of the pond of that plant. This relationship may be expressed by the following basic hydro steam co-ordinating equation

$$\frac{dc}{dg_s}\left(\frac{\dot{L}}{\dot{q}}-\frac{dg_h}{dq}\right)=N \tag{1}$$

Further, the incremental hydro equivalent dg_h/dq in equation 1 may be expressed as

$$\frac{dg_h}{dq}=\frac{\partial g_h}{\partial q}+\frac{\partial g_h}{\partial H}\left(\frac{(q-r)\frac{dP}{dS}}{\dot{q}}-\frac{dI}{dq}-\frac{dM}{dq}\right) \tag{2}$$

Equation 2 substituted in equation 1 results in

$$\frac{dc}{dg_s}\left\{\frac{\dot{L}-(q-r)\frac{\partial g_h}{\partial H}\frac{dP}{dS}}{\dot{q}}-\left[\frac{\partial g_h}{\partial q}-\frac{\partial g_h}{\partial H}\left(\frac{dI}{dq}+\frac{dM}{dq}\right)\right]\right\}=N \tag{3}$$

which for $\dot{q}=0$ becomes

$$\frac{dc}{dg_s}\left\{\frac{\ddot{L}+\left(\dot{r}\frac{dP}{dS}-(q-r)^2\frac{d^2P}{dS^2}\right)\frac{\partial g_h}{\partial H}}{\ddot{q}}-\left[\frac{\partial g_h}{\partial q}-\frac{\partial g_h}{\partial H}\left(\frac{dI}{dq}+\frac{dM}{dq}\right)\right]\right\}=N \tag{4}$$

Although the method of co-ordinating hydro and steam generation for maximum combined economy as developed here was specifically investigated on the basis of drawdown and refill of the pond of the hydro plant over the period of operation under study, the application of that method of co-ordination to such combined operation is not limited to that basis of pondage operation; it is equally applicable to the problem of determining the most economical operation to be followed in going from any given beginning pond elevation at any time to any given ending pond elevation at some predetermined future time, e.g., in the following of a rule curve. In fact, it is particularly applicable to the problem of determining the rule curve itself such as to result in the optimum co-ordination of hydro and steam generation in the seasonal operation of a reservoir.

Further, it will be noted that, regardless of the number of hydro plants on a system, the incremental steam cost to be used at any time with respect to each of such plants should be the same except for the possible effect of incremental transmission losses. In addition, when two or more hydro plants are on the same stream, the inflow into the ponds of each of the downstream plants is flatter than the discharge of the plant immediately upstream and, also, there is a time lag between such pond inflows and plant discharges unless the upstream plant discharges directly into the pond of the downstream plant. In the latter case, the inflow into the ponds of each of the downstream plants is equal to the discharge of the plant immediately upstream except for possible additional inflow between the two plants.

These hydro steam co-ordinating equations are in such forms that they can be used directly (i.e., without modification) to interrelate the hydro and steam generation and, also, the generation among the various hydro plants of a system for

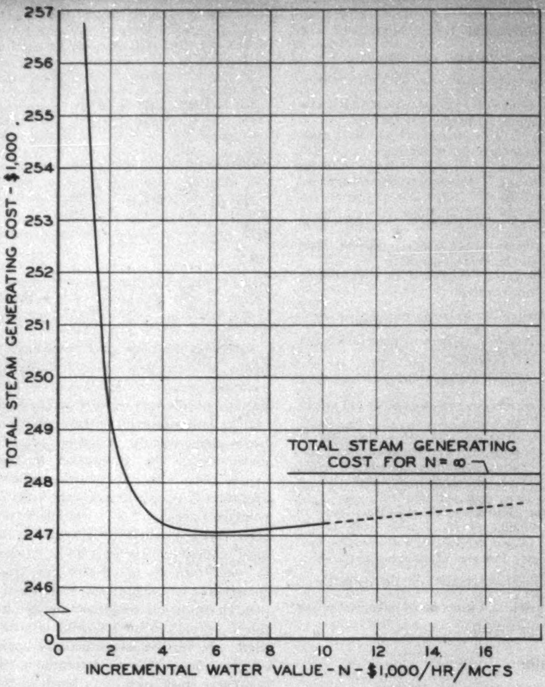

Fig. 1. Total system steam generating cost versus incremental water value N

optimum results regardless of their number, location on the system, type, etc., unless it is desired also to compensate for the effect of incremental transmission losses. This latter problem is beyond the intended scope of this paper but, considering the relatively high state of the development of methods for handling the companion problem as related to all-steam systems,[9–11] it may be expected that comparable results, as related to such losses, are also obtainable with respect to combined hydro and steam systems.

Method of Investigation

The mathematical model of the combined hydro and steam system used as the basis for this investigation may be represented by the following indicated equations

$$c=f(g_s) \qquad (5)$$

For a lossless transmission system g_s results in

$$g_s=L-g_h \qquad (6)$$

$$L=F(t) \qquad (7)$$

$$g_h=\phi(q,H) \qquad (8)$$

$$H=P\text{-}I\text{-}M \qquad (9)$$

$$P=\Phi(S) \qquad (10)$$

$$I=\beta(q) \qquad (11)$$

$$M=\gamma(q) \qquad (12)$$

$$S=\theta(q,r,t) \qquad (13)$$

$$r=\lambda(t) \qquad (14)$$

$$q=\rho(t) \qquad (15)$$

The system thus represented was operated on many different bases in an endeavor to determine a systematic basis which would result in minimum total steam generating cost over a period of time for which the operation was such that the total water used during that period was some predetermined amount. Many experiments finally indicated that optimum results are obtained when the hydro plant is operated at some constant incremental water value in accordance with equation 1 as more fully expressed by equation 3.

The relationships indicated were determined in the following manner: first, with respect to equation 5

$$\frac{dc}{dq}=\frac{dc}{dg_s}\frac{dg_s}{dq}=N \qquad (16)$$

and from equations 6 and 7

$$\frac{dg_s}{dq}=\dot{L}\frac{dt}{dq}-\frac{dg_h}{dq} \qquad (17)$$

then, rearranging

$$\frac{dg_s}{dq}=\frac{\dot{L}}{\dot{q}}-\frac{dg_h}{dq} \qquad (18)$$

which substituted in equation 16 results in equation 1.

Then, from equation 8

$$\frac{dg_h}{dq}=\frac{\partial g_h}{\partial q}+\frac{\partial g_h}{\partial H}\frac{dH}{dq} \qquad (19)$$

and from equations 9, 11, and 12

$$\frac{dH}{dq}=\frac{dP}{dq}-\frac{dI}{dq}-\frac{dM}{dq} \qquad (20)$$

Also, from equation 10

$$\frac{dP}{dq}=\frac{dP}{dS}\frac{dS}{dq} \qquad (21)$$

and from equation 13

$$\frac{dS}{dq}=(q-r)\frac{dt}{dq} \qquad (22)$$

Then, rearranging equation 22 and substituting it in equation 21 and substituting that resulting equation in equation 20 yields

$$\frac{dH}{dq}=\frac{(q-r)\frac{dP}{dS}}{\dot{q}}-\frac{dI}{dq}-\frac{dM}{dq} \qquad (23)$$

which substituted in equation 19 results in equation 2.

Equation 3 is continuous when the numerator of the first expression within the braces thereof is equal to zero at the same time that the denominator $\dot{q}$, is also equal to zero, since that expression is then in the indeterminate form and may be evaluated by differentiating both its numerator and denominator with respect to t, which reduces it to the first expression within the braces in equation 4.

There is no definite solution to equation 3 since it is solvable for all values of N, for which, however, there is only one of such values that results in the optimum over-all system operation. The value of N that results in such optimum system operation is determinable by means of successive approximations with the solution of the equation best done graphically for the purposes here. Such a solution is illustrated in the Appendix.

Conclusions

Various other systematic bases for co-ordinating hydro and steam generation were determined and investigated but none resulted in as low a cost as that obtained with the application of the basic hydro steam co-ordinating equations expressed as equations 1 and 3. It was therefore concluded that these co-ordinating equations were probably the answer to the problem even though it has not been found possible to establish a rigorous basis for this conclusion. It, nevertheless, is believed that if they actually do not provide such fundamental basis for co-ordinating hydro and steam generation for maximum economy, they at least result in sufficiently close answers to be so used for all practical purposes. In any event, it is hoped that the material presented may contribute in some measure to the eventual solution of what appears to be a rather difficult and complex problem.

It is quite probable that any practical use of the equations presented should be made by means of automatic controls or some simplification of the basic method itself, because, even with but one hydroplant, it is believed that these co-ordinating equations are too complicated to be used for direct manual application. The justification of the use of these hydro-steam co-ordinating equations would, of course, depend on an evaluation of the results obtained with their application as compared with the results obtained with other bases of co-ordinating hydro and steam generation. However, in this regard, Fig. 1, in which the smaller values of *N* are for the more peaked hydro generation which frequently is thought of as being the more desirable basis for co-ordinating hydro and steam generation, shows that the total cost of system steam generation may increase very sharply under some circumstances with such more peaked hydro generation. On the other hand, this figure also shows that the optimum value of *N* is not particularly critical since the curve is fairly flat over a rather wide range of values of *N*. It is consequently believed that numerical integration and differentiation should give satisfactory results in any application of these co-ordinating equations to actual conditions.

Appendix. Determination of the Optimum Value of N

The solution of equation 3 to determine the value of *N* such that the optimum operation results is illustrated by Table I and Fig. 2.

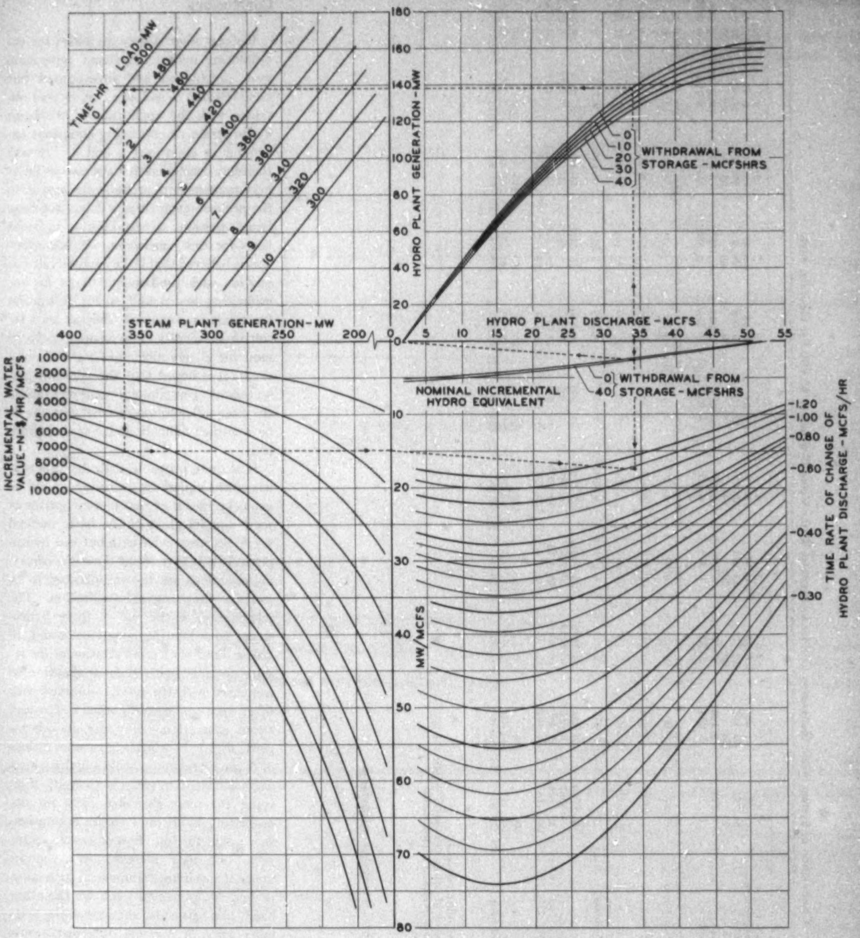

Fig. 2. Curves for the graphical solution of equation 41

The curves in the first quadrant of Fig. 2 show the hydro plant generation versus its discharge for various amounts of withdrawals from storage. They were obtained from equation 8 written as

$$g_h = -10+(0.1q-0.00001q^3)H \qquad (24)$$

where equation 9 is taken to be

$$H=56-0.1S-0.2q \qquad (25)$$

The second quadrant merely provides a graphical means of subtracting the hydro generation, obtained from the curves shown in the first quadrant, from the total system load as of various whole values of time t as given by equation 7 written as

$$L=500-20t \qquad (26)$$

These equations were found to result in the required steam generation varying over a wide enough range of system steam generating cost so that a short period of operation, 10 hours, could be used so as to minimize the necessary calculations as much as reasonably possible since all the calculations were made manually with desk calculators and, at the same time, it would be a sufficiently long enough period so as to reflect satisfactorily the effect of all the factors involved.

The curves in the third quadrant of Fig. 2 are each for various assumed constant values of N as shown. These curves are functions of the steam generation and are in units of mw per mcfs, as shown. They are obtained by dividing such assumed values of N by the incremental steam cost for the various values of steam generation shown. Then, writing equation 5 as

$$c=20+3g_s+0.01g_s^2+0.001g_s^3 \qquad (27)$$

results in

$$\frac{dc}{dg_s}=3+0.02g_s+0.003g_s^2 \qquad (28)$$

Equation 27 results in tremendously high steam generating costs for the larger values of generation, but this is of no particular significance since in this paper only the basic principles for the correct operation of combined hydro and steam systems in general are being determined rather than the correct operation of any particular system. This characteristics of such high values of steam generating costs is necessary because, based on the arithmetical method of investigation and the short period of time (10 hours) of operation used in the study to facilitate the calculations, it would thereby be sufficiently responsive to differences in total costs so as to provide a reasonable basis for a sound conclusion.

Then, to illustrate, for a required steam generation of 300 mw for which, from equation 28, the incremental steam cost is $279 per hour per mw and for a value of N of $5,000 per hour per mcfs, the corresponding value resulting therefrom and to be plotted with respect to the vertical scale between the third and fourth quadrants is 17.92 mw per mcfs and is obtained as $5,000 per hour per mcfs divided by $279 per hour per mw.

Two quantities are shown plotted in the fourth quadrant of Fig. 2: the first expression within the braces of equation 3; 2. the nominal incremental hydro equivalent which is the second expression within the braces of that equation.

Then, from equation 26

$$\dot{L}=-20 \tag{29}$$

and from equation 24

$$\frac{\partial g_h}{\partial H}=0.1q-0.00001q^3 \tag{30}$$

Then, as included in equation 25

$$P=56-0.1S \tag{31}$$

from which

$$\frac{dP}{dS}=-0.1 \tag{32}$$

For equation 14 written as

$$r=30 \tag{33}$$

and substituting equations 29 through 33 in the first expression within the braces of equation 3 results in

$$\frac{-20+0.1(q-30)(0.1q-0.00001q^3)}{\dot{q}} \tag{34}$$

which is shown plotted in the fourth quadrant of Fig. 2 as a function of q for various values of $\dot{q}$, as shown to the right of that quadrant.

Also, from equations 24 and 25

$$\frac{\partial g_h}{\partial q}=(0.1-0.00003q^2)(56-0.1S-0.2q) \tag{35}$$

Then, as included in equation 25

$$I=0 \tag{36}$$

and

$$M=0.2q \tag{37}$$

from which

$$\frac{dI}{dq}=0 \tag{38}$$

and

$$\frac{dM}{dq}=0.2 \tag{39}$$

Substituting equations 30, 35, 38, and 39 in the second expression within the braces of equation 3 yields

$$(0.1-0.00003q^2)(56-0.1S-0.2q)-0.2(0.1q-0.00001q^3) \tag{40}$$

which is also shown plotted in the fourth quadrant of Fig. 2 as a function of q for various values of withdrawals from storage S; only two are shown in the figure.

Expression 40 or the second expression within the braces of equation 3 is in the exact nature of the over-all plant incremental hydro equivalents used for many years in various studies in that it only takes into account the unit characteristics of some given head and the incremental head losses as related to the intake and tail-race and disregards the incremental head losses related to withdrawals from storage. The effect of this latter factor should also be included as shown in equation 2 which expresses the true incremental hydro equivalent. The determination that factors should be included in the expression for the incremental hydro equivalent, equation 19, to account for the incremental head losses resulting from withdrawals from storage as shown in equation 23 and that a factor should be included in the hydro steam co-ordinating equation itself, equation 1, to account for the effect of the time rate of change of the load to be supplied are new in so far as it is known to the author. These determinations proved to be the whole key to the problem as finally resolved. Then, since expression 40 is not actually the true incremental hydro equivalent, it is referred to, for convenience, as the nominal incremental hydro equivalent.

The use of Fig. 2 in solving equation 3, with equation 28 and expressions 34 and 40 substituted in it, which results in

$$(3+0.02g_s+0.003g_s^2)\left[\frac{-20+0.1(q-30)(0.1-q0.00001q^3)}{\dot{q}}-[(0.1-0.00003q^2)(56-0.1S-0.2q)-0.2(0.1q-0.00001q^3)]\right]=N \tag{41}$$

is illustrated in Table I where the first step is to assume a value for the hydro plant discharge q for $t=0$. This is shown as 34.171 mcfs in line 3 of Table I for the conditions there. A line is then drawn vertically into both the first and fourth quadrants for this value of hydro plant discharge, as shown by the dotted line in Fig. 2. Next, a line is drawn from the point of intersection of this vertical line and the curve for the nominal incremental hydro equivalent for the withdrawal from storage for the time t under consideration to the origin, as shown in the fourth quadrant. A second line is then drawn horizontally from the point of intersection of this same vertical line and the curve for the hydro generation for the same withdrawal from storage for the same time t as in the foregoing, as shown in the first quadrant, into the second quadrant to the load for the time under study, at this point for $t=0$. Next, a vertical line is drawn downward from this point into the third quadrant to the intersection with the curve there for the assumed value for N, $6,000 per hour per mcfs in this case, as shown in line 7 of Table I. Then, proceed horizontally to the right from this point of intersection to the intersection with the vertical line through the origin between the third and fourth quadrants; from which latter point of intersection a line is drawn parallel to the line originally drawn from the nest of curves of the nominal incremental hydro equivalents through the origin to the point of intersection with the vertical line originally drawn through the assumed discharge of the hydro plant. This latter point of intersection determines the value of $\dot{q}$, as shown in line 8 of Table I for $t=0$. This initially determined value of $\dot{q}$ is also entered in line 2 of Table I.

The runs for all the following values of t start with assumed trial values of $\dot{q}$, as shown in line 2 of Table I, rather than with an assumed value of hydro plant discharge as for $t=0$. The values of hydro plant discharge for these succeeding hours are computed as shown by note B to line 3 of Table I, based on the assumed values of $\dot{q}$ of line 2. The resulting withdrawals from storage, based on these values of hydro plant discharge, are then computed as shown in line 6. Based on these data of hydro plant discharge and withdrawals from storage values of $\dot{q}$ are determined from Fig. 2 in the same manner as just described with respect to $t=0$, and the values of these quantities thus determined are entered in line 8. They should check the values assumed for q of line 2 for the same value of t. If they do not, new values of $\dot{q}$ should be assumed for line 2 and the procedure repeated with respect to each value of t, in order, until the values determined with respect to line 8 check those assumed for line 2. It was found that this check was usually obtained on the second trial for most of the values of t. These calculations are repeated for the whole of the period under study and should result in zero withdrawal from storage at the end of the period of operation, or as close thereto as it is practicable to obtain, −0.0025 mcfs-hours in the case illustrated by Table I. If the withdrawal from storage at the end of the period of operation is not nearly equal to zero, a new run should be made beginning with a new trial initial value for the hydro plant discharge for $t=0$, and the whole process should be repeated until the desired conditions are met.

The middle portion of Table I, beginning with line 9, was prepared as a basis for determining the total cost of the steam generation for the whole of the period of operation with a high degree of precision so as to provide the most reliable basis practicable for a sound conclusion. The equation for q, shown on line 10 under the derivation column of Table I, was assumed as

$$q=q_1+2q_2t+3q_3t^2+4q_4t^3+5q_5t^4 \tag{42}$$

There seemed to be no basis for readily determining any theoretically exact equation for this quantity. However, this statement of the hydro plant discharge as a function of time is believed to be sufficiently close, for the purposes here, to any theoretically exact equation that may actually exist with respect to the conditions under investigation so that any differences there may be between it and what might otherwise be the correct form of equation for this quantity with respect to such conditions would not be of any practical or possibly even of any theoretical significance as to such purposes.

The equation for $\dot{q}$, shown on line 9 under the derivation column of Table I, was determined, first, from equation 42 as

$$\dot{q}=2q_2+6q_3t+12q_4t^2+20q_5t^3 \tag{43}$$

Second, as to the specific values for the coefficients $2q_2$, $6q_3$, etc., shown on Table I, they were solved for simultaneously as based on the values for $\dot{q}$, shown for $t=0$, $t=3$, $t=6$, and $t=9$ on line 8.

All the coefficients of equation 42, except q_1, are then determinable from the results obtained in the determination of the coefficients for equation 43. Since the operation is assumed to be on the basis of returning the pond to the same elevation at the end of the period of operation under study as at the beginning of such period, the total plant discharge during the whole of that period is equal to the total pond inflow during such period. Then, if for the purpose of this investigation, but not otherwise limited thereby, constant pond inflow during the period of operation is assumed, as shown by equation 33

$$\int_0^T q\,dt=\int_0^T (q_1+2q_2t+3q_3t^2+4q_4t^3+5q_5t^4)dt=\int_0^T r\,dt \tag{44}$$

from which, performing the indicated operations

$$q_1T+q_2T^2+q_3T^3+q_4T^4+q_5T^5=rT \tag{45}$$

which results in

$$q_1=r-q_2T-q_3T^2-q_4T^3-q_5T^4 \tag{46}$$

The quantity q_1 is then readily determinable from this latter equation and the coefficients are determined for equation 43 as in the foregoing. The determination of the correct values for these coefficients is very important in this study since precisely the same total amount of water will thereby be assured to be used during the period of operation for each of the various bases of operation investigated. This will then result in no one of such methods of operation being at any advantage or disadvantage as compared with any other as related to the amount of water used since, otherwise, it might be difficult to reach a sound conclusion.

The equation for the withdrawals from storage S, as shown on line 11 under the derivation column of Table I, was determined in the following manner with respect to equation 42

$$S=\int_0^t (q-r)dt=\int_0^t (q_1-r+2q_2t+3q_3t^2+4q_4t^3+5q_5t^4)dt \tag{47}$$

from which, performing the indicated operations

$$S=(q_1-r)t+q_2t^2+q_3t^3+q_4t^4+q_5t^5 \tag{48}$$

The balance of Table I is believed to be readily followed from what is shown there except possibly the determination of the total cost for the period of operation as shown at the bottom. Two of such determinations are shown, one is based on trapezoidal summation which results in a total cost of $247,386, and the other is based on a more exact integration which results in a total cost of $247,026, or a difference of $360. An investigation showed that this latter basis of determination of such cost is much more nearly correct than that based on trapezoidal summation. The equation for the rate of cost c' is based on the values of c on line 18 for the even values of t, and is shown in the next to the last line at the bottom of Table I. The coefficients for this equation were solved for simultaneously as based on such values of c.

Fig. 1 shows the total costs for the same conditions as in the foregoing except for different values of N. These results were determined in the same manner as shown on Table I and were also based on Fig. 2. Fig. 1, in which the smaller values of N are for the more peaked hydro operation, and, for which, with $N=\$\infty$ per hour per mcfs the hydro plant discharge is equal to a constant pond inflow, shows that it is necessary to make computations of the total system cost for different assumed values of N, and then to determine the value of N that results in the minimum of such cost. It is determined from this figure that, for all practical purposes, the optimum value of N is that for which Table I is computed, $6,000 per hour per mcfs. Every other systematic basis for controlling the operation that it was found possible to devise, and which were all investigated, resulted in larger total cost than the $247,026 shown determined there.

◆

Discussion

F. L. Lawton (Aluminium Laboratories Limited, Montreal, Que., Canada): The author is to be congratulated on a constructive presentation which clearly sets out the problems involved in co-ordinating hydro and steam generation in a complex power system for optimum economy. The problem is a difficult one but the author has succeeded in so developing thinking that, while not a finished method or tool for application by power engineers, it is a distinct forward step, and one which has been badly needed for a long time.

D. B. Klapper (Commonwealth Edison Company, Chicago, Ill.): Mr. Watchorn's development of a procedure for co-ordinating operation of separate steam and hydro plants is a significant step in the search for methods of reducing power system operating costs. It appears that the method used by the author may possibly be extended to cover an unsolved problem arising in systems supplied entirely by steam plants. This problem centers around the determination of proper allocation of fixed total available fuel supplies of different costs and heat content; namely, the station incremental rate for a given station is not entirely dependent upon that particular station's output, but is also dependent upon anticipated loading of other steam plants within the system.

Table II

	Hydro	Steam
Energy available	variable pondage	variable heat content and storage tonnage
Cost of losses	in tail-race, etc.	in transportation of fuel to different stations

The similarity between Mr. Watchorn's problem and the one just mentioned is based on the possible analogies given in Table II.

Concerning the application of Mr. Watchorn's method to combined steam and hydro systems, it should be pointed out that the solution of equation 3 or 4 is a problem in the variational calculus, which is dependent upon the class of "admissible function" assumed as possible solutions. The trial-and-error method used to obtain minimum costs may require a large number of iterations, particularly since a considerable amount of time may be wasted finding only relative minimums rather than the absolute minimum. Even then, there may still exist some doubt as to whether another class of functions may not result in lower costs; e.g., $N=N(t)$ rather than $N=$constant as assumed in the paper. A cyclic function (of time) for N appears to be a possibility. Although this would add a considerable amount of work, it might result in final savings.

R. H. Miller (Pacific Gas and Electric Company, San Francisco, Calif.): The subject of co-ordination of hydro and steam generation is one which merits a great deal of study. Considerable interest has been shown in the past few years in economic loading of steam generating units and consideration of transmission losses in over-all economic operation of power systems.

The co-ordination of steam and hydro generation is a logical extension of this subject and the approach that the author has taken seems to be a logical one. Frequently, operation of hydro and steam is done by rule of thumb, and it has not been possible to be certain that maximum over-all economy results from such a method of operation. It is apparent from the mathematical derivations in the paper that a solution for the most economical operation of co-ordinated hydro and steam generation is complex. By resorting to curves derived from the mathematical equations, Mr. Watchorn has been able to arrive at optimum conditions for hydro and steam generation where the total hydro and steam can be considered as being lumped.

A system such as that of the Pacific Gas and Electric Company consisting of 47 hydro and 18 steam plants spread over a large geographical area presents a very complex problem. The hydro plants vary in head from less than 50 feet to over 2,500 feet and include both stream flow and storage operation.

Considering also the factors involved in water regulation such as storage rights and requirements necessary for release for domestic and irrigation uses which must be correlated, if possible, with power generation, a solution of the problem of most economic utilization of water is very difficult. All of these problems are further compounded when transmission losses are considered. It appears that the author's conclusion that the basic equations can be practically applied only by the means of a computer or by automatic controls is well founded.

It is hoped that further work will be done along the line of co-ordination of hydro and steam generation so that practical and simplified methods of solution to the problem may result as undoubtedly there are economies to be achieved.

G. J. Vencill (Union Electric Company of Missouri, St. Louis, Mo.): Co-ordination of hydro and steam generation to supply the needs of an electric power system has been necessary since the early days of the industry in order to realize economies and minimize operating costs. We have operated our facilities to what we thought was the best advantage by comining applicable data with rules of thumb and best judgment without reducing the procedure to substitution in a mathematical equation.

The method developed and presented by the author takes into account use of stored water and the effect of plant flow or tail water level with the resultant head. Many other factors must be evaluated before an answer can be obtained, and we are doubtful that a practical system of automatic controls can be devised to do this on the Union Electric system. In addition to the fundamental hydraulic factors, consideration must be given to possibility of future runoff as determined from weather conditions and weather forecasts, and to governmental regulations which affect our use of storage. The necessity of altering load schedules to accommodate a heavily loaded towboat bound upriver has upset many a well-laid plan for hydro operation. With such factors as these, in addition to variable hydro turbine efficiencies over a range of loads, and the difficulty in precise determination of steam generation incremental costs over a narrow range of output, the difficulties in reducing all the elements to a form suitable for automatic calculation seem insurmountable. Even when a perfect hydro schedule is determined by balancing all physical factors, the effect on fuel commitments, delivery schedules, use of available dump gas, etc., sometimes dictates changes. The possible combinations introduced by considering more than one hydro plant would be considerable.

Undoubtedly the rigorous exploration of the many facets of this problem by mathematical means is interesting and may lead to approximations which are useful, but the complex and indeterminate nature of many of the elements would seem to make their automatic calculation impractical.

P. L. Dandeno and W. G. Chandler (Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): The author states in the conclusions that various other systematic bases for co-ordinating hydro and steam generation were determined and investigated but none resulted in as low a cost as his own.

The discussers, in co-operation with the G. E. Company, have been carrying on a similar program of investigation on the Ontario Hydro System (see reference 1 of the paper). This has involved the problem of scheduling three steam plants and four hydro plants on a co-ordinated basis. The digital methods originally outlined in 1954 by Glimn, Kirchmayer, Habermann, and Thomas[1] have been applied, both with and without the effect of transmission losses. Needless to say, the problem becomes less complicated when not considering transmission losses, and when the number of hydro plants to be scheduled is reduced to one only the amount of work is further reduced.

We would like to ask Mr. Watchorn whether he specifically considered the methods outlined in reference 1 of the paper. These methods have a rigid theoretical basis for their application. Admittedly, these methods at present cover only the constant head hydro problem. It has been our experience, however, that the shape of the incremental water rate curve for hydro plants remains practically invariant over a ±5-per-cent range in head with small changes, of course, in actual value of the curve as head varies. This range in head applies to a generating station with a reasonably large pondage back of it. Bearing these factors in mind, the assumption of constant head is reasonably valid and we have proceeded with good results on this basis.

We note with interest the value N employed by Mr. Watchorn which he states is the incremental water value in dollars per hour per 1,000 cubic feet per second. This is analogous to the value γ referred to in reference 1 of the paper. This value γ, multiplied by the incremental hydro plant rate (usually given in mw per cubic feet per second), gives an equivalent hydro incremental rate in dollars per mw-hour. This could be readily compared with the usual steam plant incremental characteristic in dollars per mw-hour. The latter is derived from the incremental heat rate in Btu per mw-hour and the cost of fuel in dollars per million Btu. Thus γ can be determined and is in dollars per million cubic feet. We feel that this latter method of specifying water values is a clearer one than that suggested by Mr. Watchorn and is directly comparable to the usual steam values used. By choosing γ, usually by trial and error, in such a manner that the desired amount of water is used, the standard co-ordination equations result. A typical value of γ for our Des Joachims plant, 134-foot head and 27,500-cubic-foot-per-second average daily flow, is \$9.00 per million cubic feet.

These equations could be easily solved graphically when not considering transmission losses and digital means could be employed when the more complex problem of including losses is under consideration. If losses are not included and only one hydro plant is considered, the parameters employed in the hydro-steam solutions are those which are usually met in the straight steam solution.

If Mr. Watchorn has any further comments on his reasons for establishing another set of equations, we should be most interested in hearing about them.

1. AUTOMATIC DIGITAL COMPUTER APPLIED TO GENERATION SCHEDULING, A. F. Glimn, K. L. Kirchmayer, R. Habermann, Jr., R. W. Thomas. *AIEE Transactions*, vol. 73, pt. III, Oct. 1954, pp. 1267–75.

C. W. Watchorn: I wish to thank all the discussers for their contributions with respect to a very complex problem. As stated by Mr. Lawton, methods have been badly needed for a long time for the co-ordination of hydro and steam generation. However, the problem is too complicated for the human mind of itself alone to even begin to cope with it and the time is past when we should consider any way of handling it, where the hydro plants involved are of any appreciable size, other than by the application of automatic computers.

Mr. Klapper is quite right in his conclusion that the method described in the paper as being used in the investigation of the fundamental relationships to be observed in the co-ordination of hydro and steam generation for optimum results has wider application than to just that problem. What was really done was to determine the form of the relationships that should be observed among the several factors involved in such co-ordination as a special case only of the general problem for which the manner of use of the energy available from any source is a factor in its co-ordination with otherwise normal steam generation (at least as we know it today) so as to obtain maximum economy. The specific forms that such relationships will take for different conditions or situations will differ as the factors involved and their interrelationships differ with respect to each of such conditions and situations, but the fundamental basis for their determination, nevertheless, should be essentially the same as that described in the paper.

Although I am skeptical that N should be other than a constant, as assumed in the paper, Mr. Klapper's suggestion that it may actually be a variable in order to result in minimum costs is an interesting possibility. However, in the same way that practical considerations, such as the uncertainties of future loads, river flows, etc., together with the flatness of the minimum cost–N relationship itself in the vicinity of absolute minimum cost, as shown in Fig. 1, do not require that N must be determined exactly with respect to such minimum cost, it may be that any additional reductions in total cost that may be obtainable under such conditions with N as a variable as compared with its being assumed to be a constant would be of comparatively little practical significance. However, an investigation of such possibilities would be most interesting.

The complexity of the system described by Mr. Miller demonstrates the need for a systematic basis for co-ordinating hydro and steam generation. The requirements for such co-ordination, as well as the requirements for water release for purposes other than for power production, except for the effect of incremental transmission losses, are fully met by the co-ordinating equations presented in the paper. In the event that the water released for such other purposes is also to be used for generation, such use is a factor in the determination of the total withdrawals from storage from time to time, whereas, in the event the water that is thus required to be released is to be a diversion, such use is equivalent to a reduction in river flow or pond inflow, even to the extent that such latter quantities may then, in effect, actually become negative.

There is no doubt but that the problem is a difficult one as more specifically outlined by Mr. Vencill. The uncertaintites as to future loads and river flows, and, it might be added, also as to the future availability of generating capacity, including the future availability of steam capacity, etc., exist regardless of the method used for the co-ordination of hydro and steam generation, but it is believed that a minimum of difficulties, in the sense of obtaining maximum economy, will be experienced because of such uncertainties with the application of the method of co-ordination suggested in the paper as contrasted with other possible methods of such co-ordination. This is believed to be so because, regardless of the method of co-ordination used, reappraisals are required to be made from time to time for best results, and then should be followed by the necessary readjustments of the operation, which are possibly less drastic with the suggested method of co-ordination, since, according to Fig. 1, the value of N is not at all critical.

My answer to Mr. Miller's discussion relative to the problems related to the requirements for water release other than in accordance with the best use for power production applies equally to Mr. Vencill's discussion. Subject to an evaluation, as suggested in the paper, very well worthwhile benefits may very possibly be realized as the result of the application of the suggested basis of co-ordination, or of some simplified version of it, in spite of such uncertainties and resulting difficulties, thereby possibly justifying the application of such a systematized basis of co-ordination, it being recognized that it is desirable to resist the temptation to sacrifice justifiable accuracy for mere simplicity. It is not enough to develop something that is simple merely because it is simple; rather, if it is to be simple it is preferable that it be a simplification of something we really know about.

There is really no conflict of which I am aware between the current paper and that of reference 1 of the paper. The present paper had been well under way for over 2 years when reference 1 first became available in 1953. It was hoped then, when that paper first became available, that it might provide the answer to the general problem treated in the current paper which had concealed its secrets so stubbornly so long. It was soon realized that this hope was not to be so easily fulfilled, since, as stated both in that paper and by Mr. Dandeno and Mr. Chandler, it was intended that that paper was to provide for the co-ordination of hydro and steam generation and transmission losses only for the limited condition for which the head remained constant, whereas the current paper was intended to provide for the more general relationship with respect to the co-ordination of hydro and steam generation without any limitations whatsoever on the hydro plant characteristics, but treating the co-ordination of transmission losses as a separate problem beyond the scope of the paper.[1] It is believed that the equations of both papers will give the same results in the co-ordination of hydro and steam generation for maximum economy with an assumed constant head hydro plant assumed to be operated on the same bus as the system steam plants. Thus, the co-ordinating equation of the earlier paper is, in effect, a simplification of the more general equation of the current paper when the appropriate conditions obtain. Then, if for no other purpose, the more general equation provides a basis for the measurement of the effect of whatever simplifications it is desired to investigate, or, putting it another way, before we attempt to make anything simple, we should know what we are simplifying and what the effects of such simplifications are with respect to the particular surrounding circumstances.

Thyrite Protection for Series Windings of Autotransformers

J. W. ALBRIGHT
ASSOCIATE MEMBER AIEE

THE application of surge voltage to the series winding of an autotransformer presents unique transient-voltage problems which are generally more severe than encountered in transformers with electrically separated windings. When a pulse is applied to the high-voltage terminal of an autotransformer, almost all of the voltage appears across the series winding, even though the turns in the series winding may be only a fraction of the total turns from high-voltage terminal to ground. The resultant high internal transient-voltage oscillations in the winding often make the problem of providing the required amount of insulation extremely difficult.

Furthermore, the magnitude of the internal voltage transients can be influenced to a large degree by the terminal conditions of the series winding during the period that the surge voltage persists. This phenomenon makes possible a situation where an autotransformer designed to withstand voltage surges of a given magnitude with certain terminal conditions, and demonstrated by factory test to have adequate insulation for that condition, could fail in service when subjected to a surge of the same magnitude if the terminal conditions were substantially different.

A practical example of a situation where the terminal condition may be significantly different in service than during the factory test is the case where a by-pass gap or lightning arrester is connected across the terminals of the series winding to limit the voltage which may

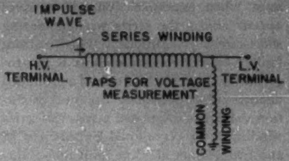

Fig. 2 (right). Diagram of electromagnetic model used for tests

appear across it. In this paper it will be shown that such a practice does not improve the internal winding stresses, but actually increases them with respect to voltage to ground, if shielding is not utilized to control the voltage distribution in the winding. Unless the autotransformer is properly designed to allow for this effect and the factory impulse test is designed to simulate the by-pass gap sparkover or lightning arrester operation, a potential service hazard can be created.

Simulation of the service conditions in text is, itself, a difficult problem. Where both the high- and low-voltage terminals are insulated for the same voltage level, an effective test can be obtained by short-circuiting both terminals together. If they are insulated for different levels, an elaborate voltage-divider arrangement is required to limit the voltage across the series winding to a value equal to that permitted by the protective device. Although the actual protective devices could be installed on the autotransformer for the test, the wave-shape changes produced on the impulse oscillograms by the operation of the devices largely destroy the usefulness of the oscillograms for failure detection purposes.

In this paper it will also be shown that shielding the series winding greatly reduces the internal transient-voltage oscillations. Shielding may be accomplished electrostatically, or by means of internally mounted Thyrite* shunting resistors interconnected with the winding. When the Thyrite is connected to the winding at regular intervals, essentially linear voltage distribution is obtained and internal transient-voltage oscillations are effectively eliminated. Control or elimination of internal voltage transients in this manner generally obviates the need for external by-pass devices connected across the series winding. However, in special cases where advantage can be gained from their use, the addition of such devices does not change the distribution of voltage within the shielded winding.

Series Winding Transients

The impulse voltages applied to the high-voltage terminals of an autotransformer are determined by the basic insulation level of the system, but the turns in the series winding are based upon the coratio, or per-unit difference in voltage rating of the series and common terminals, as illustrated in Fig. 1. It has been shown[1] that, when a surge impinges on the high-voltage terminal, practically all of the voltage appears across the series winding when a resistance representative of the surge impedance of the load connected to the autotransformer in service is connected from the common terminal to ground. This means that the impulse "volts per turn" are greater than in a comparable 2-winding transformer, and the component of the voltage transients developed in the windings which depend primarily upon electromagnetic induction are correspondingly higher. The most severe problem usually is encountered when taps are provided in the series winding.

When taps are required to change the voltage rating of the high-voltage terminal, they must be physically located in the series winding to avoid changing the voltage rating of the low-voltage terminal also. The turns tapped out must be the required percentage of the total turns in the series and common windings, but, since only a fraction of the turns are in the series winding, the percentage of the series winding turns tapped out is much greater.

For example, in an autotransformer rated 138,000 grounded wye/115,000 grounded wye with a ±5-per-cent tap range on the high-voltage terminal, the total tap range of 13.8 kv represents 46 per cent of the turns in the series winding. On minimum turns connection, the idle tap turns are equal to 86 per cent of the active turns in the winding. When this condition exists, the transient voltages developed across the tap range may equal or exceed the surge voltage applied to the high-voltage terminal.

The difficulty of insulating for such voltages, particularly in autotransformers with low coratio, has encouraged some use of applying by-pass spark gaps or lightning arresters to limit the voltage which can appear across the terminals of the series winding. It will be demonstrated that the use of such a spark gap or lightning arrester does not improve, and may actually increase, the internal voltages to ground and between parts of the winding unless special design features are incorporated to improve the voltage distribution of the winding.

For this reason, the General Electric Company has adopted the practice of applying internally mounted Thyrite resistors, interconnected to the winding at regular intervals to produce essentially linear voltage distribution. This practice has been in effect for approximately 15 years and has proved itself in service over that period.

The Thyrite is not designed to limit the voltage across the series winding but only to control the voltage distribution within the winding. Generally, the Thyrite alone will furnish the needed protection of the series winding without external by-pass devices. When the coratio is exceedingly low, or the tap range high, as in the example previously cited, the tap range may require excessive insulation even with linear voltage distribution. In such cases, an external lightning arrester connected across the high- and low-voltage terminals, combined with internally mounted Thyrite, may be used to reduce further the voltages in the series winding.

Application of Lightning Arrester

The rating of a by-pass lightning arrester applied in this manner must be adequate to assure valve reseal performance when excessive dynamic voltages appear across the series winding during short-circuit conditions. When certain fault conditions exist, such as a line-to-ground fault on the load side of a grounded neutral autotransformer, the total excitation voltage is impressed across the series winding. The combined impedances of autotransformer and line limit the excitation voltage to a value less than the prefault voltage, but the voltage may be several times higher than the normal operating voltage across the series winding.

---

*Registered trade-mark of General Electric Company.

Any by-pass arrester used must withstand this overvoltage. Failure of the lightning arrester to reseal would increase the severity of the short circuit by reducing the circuit impedance and thereby impose greater duty on the circuit breakers and other system components. As the failed lightning arrester would be required to carry power current for the duration of the short circuit, a fault lasting longer than a few cycles could physically destroy the arrester.

Since the by-pass arrester must be of higher valve rating than would be normally used for a system voltage corresponding to the normal operating voltage of the series winding, this by-pass arrester cannot be incorporated as an inherent part of the normal line-to-ground arresters protecting the autotransformer. Separate lightning arresters must be used from line to ground on the high-voltage and low-voltage lines to limit the value of incoming surges to magnitudes consistent with the basic insulation levels of the respective lines.

Tests

To demonstrate the effect of terminal conditions on series winding transients and the improvement obtained by shielding, a series of tests were conducted on a unity time scale electromagnetic model of a 2-winding core-type autotransformer with concentric windings, as shown in Fig. 2. The model had 15 per cent of the total turns in the series winding and 85 per cent in the common winding—representative of an autotransformer in the 138,000 grounded wye/115,000 grounded wye class. A total of 18 taps were provided in the series winding for voltage measurement purposes. The electromagnetic model technique is particularly suited to a study of this nature, as it permits a much more thorough exploration of points within the winding than can be done practically on an actual transformer. It has been demonstrated[2,3] that the accuracy of the models is well within the limits required for design purposes.

Fig. 3 shows the maximum voltages between parts, maximum voltages to ground, and initial voltage distribution of the series winding with five different conditions existing when an impulse is applied to the series terminal. The initial voltage distribution is not the true electrostatic voltage distribution, but the actual distribution of voltage to ground at approximately 2.0 microseconds with a nominal 1.5x40-microsecond wave applied. The maximum voltage to ground plots are envelope curves of the maximum voltage occurring at any time.

Fig. 3(A) shows the voltages developed in the series winding without Thyrite or rod gap connected to the terminals. The insulation problem is illustrated by the 120 per-cent maximum voltage to ground near the mid-point of the winding and the 57-per-cent voltage across 17-per-cent turns (2.5 per cent of total turns) near the one-third point of the winding.

The effect of connecting a rod gap across the series winding terminals is illustrated in Fig. 3(B). For this example, the rod gap was set to spark over when the applied wave reached 25 per cent of crest value. Note the initial voltage distribution in the first half of the winding is not changed. In the second half of the winding, the voltages are raised along a curve of approximately the same shape, but of reverse slope, as in the first half of the winding. This distribution is produced by the spark-over of the rod gap which raises the potential of the low-voltage terminal to a value near that of the high-voltage terminal. The maximum voltage to ground at the mid-point has increased to 155 per cent, and the maximum voltage between parts of the series winding (46 per cent), although decreased somewhat from the value in the previous case, occurs near the mid-point

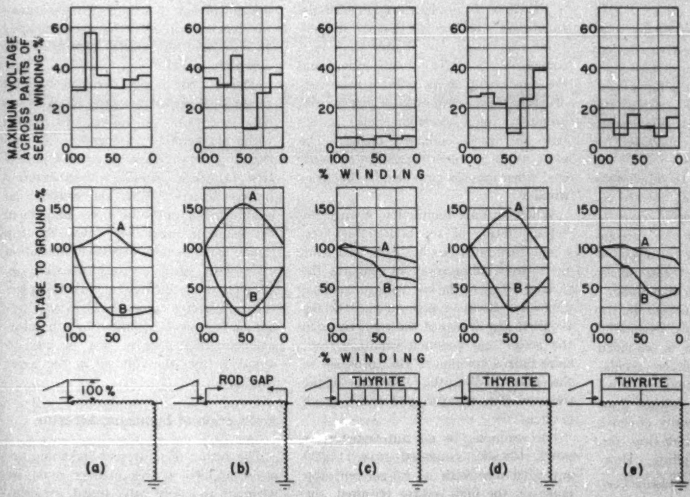

Fig. 3. Voltage distribution in series winding with 2.5x55-microsecond wave applied to high-voltage terminal

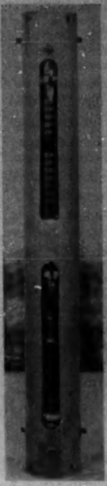
A—Maximum voltage distribution
B—Minimum voltage distribution
(a)—No protection
(b)—Rod gap across series windings
(c)—Thyrite with five interconnection points
(d)—Thyrite connected at ends only
(e)—Thyrite connected at ends and mid-point



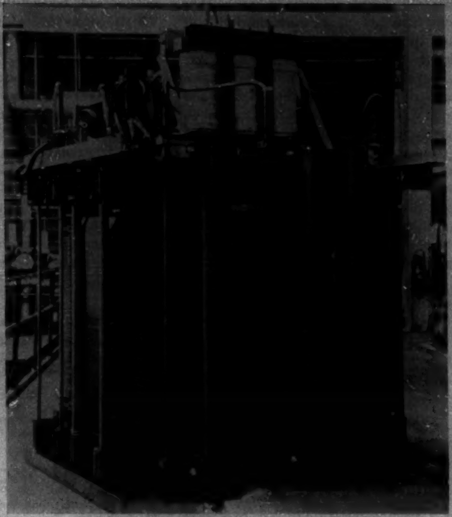


Fig. 4 (left). Thyrite stack for internal mounting in power transformers

Fig. 5 (right). Thyrite stacks applied across the winding of a 2-core 3-phase regulating autotransformer

of the winding where taps are normally located.

The spark-over of the rod gap produces an effect which is identical to that obtained by impulsing both ends of the winding simultaneously. When an impulse wave travels toward the mid-point of the winding from both ends, a reflection is produced at the mid-point which tends to double the applied voltage at that point. In this example, damping of the wave holds the reflection to less than double voltage but still permits the mid-point of the winding to oscillate to 155 per cent of the applied voltage.

Fig. 3(C) strikingly illustrates the advantage of Thyrite interconnected with the winding at several points. Both the initial and maximum voltage distribution curves are essentially uniform. The maximum voltage to ground is limited to 102 per cent, and it occurs near the line end. The voltage between parts is approximately constant throughout the winding and does not exceed 6 per cent of the applied voltage across 17 per cent of the series winding.

The effect of the interconnections between the Thyrite and winding is illustrated in Fig. 3(D). Thyrite without interconnection is similar to a lightning arrester across the terminals, and the resulting voltage transients are not significantly different from the case of a rod gap across the terminals in Fig. 3(B). The voltages to ground and between parts are somewhat less, principally because the voltage drop across the Thyrite improves the initial voltage distribution.

One interconnection between the mid-point of the Thyrite and the mid-point of the winding is illustrated in Fig. 3(E). This is an intermediate case, roughly analogous to the condition which is obtained with partial electrostatic shielding of the winding. It shows marked improvement over the case of no interconnections, but is not as effective as the multiple interconnections shown in Fig. 3(C).

Application of Thyrite

The Thyrite used in transformers is in the form of 6-inch-diameter disks, 3/4 inch thick, with nonlinear resistance characteristics similar to those used in lightning arresters. The application differs, however, inasmuch as the disks are directly connected to the winding without isolating gaps and must be able to withstand operating voltage continuously without overheating. Although this practice requires the use of several times as many disks for a given voltage as does an arrester, it has the advantage of relieving the Thyrite from dependence upon a gap structure to interrupt power-follow current before dangerous overheating occurs.

A sufficient number of disks are placed in series to limit the Thyrite temperature to a maximum of 95 degrees centigrade with the transformer delivering full load at 105-per-cent voltage. In addition to this requirement, the stack is also designed to limit the Thyrite temperature to a safe value during the factory induced-voltage test and during any system faults which may cause abnormal voltages to appear across the winding.

The adequacy of the design methods, and the stability of the Thyrite disks, have been proved by the operating record of hundreds of transformers in service for as long as 15 years without a single failure attributable to the Thyrite.

Since the Thyrite is used only to divide the voltage uniformly along the winding—not to limit the voltage across the terminals—the resistivity of the stack is not important and may vary over wide limits without affecting its performance for this application. This allows the designer complete freedom to select the number of disks in series to meet the heating requirements.

The effectiveness of the Thyrite as a voltage divider derives from its nonlinear volt-ampere characteristics[4] rather than the specific resistance of the stack. These may be expressed by

$$I = KE^N$$

where

I and E = instantaneous values of current and voltage respectively

K and N are constants depending upon the dimensions and composition of the disk

For disks used in transformers, the exponent N is in the order of 3.5; so an elevenfold increase in current merely doubles the voltage across the disk. In the application being considered, when a surge impinges on the autotransformer terminals, the current in the various portions of the Thyrite stack is different since charging current is supplied to the winding at the points of interconnection. The flat volt-ampere characteristics of the disks permit wide variations of current throughout the stack without producing a significant departure from uniform voltage distribution.

Thyrite Stacks

When a number of disks are used in series in a stack, they are mounted in a

Herkolite* tube, as shown in Fig. 4. The tube furnishes rugged mechanical support and serves as insulation to the mounting framework, tank wall, and other surrounding parts. Axial pressboard spacing strips between the Thyrite disks and tube wall provide adequate ducts for oil circulation. Copper spacing disks with extruded feet are located between all Thyrite disks to maintain electric contact while providing ventilation for maximum heat dissipation Flexible copper straps or cable are brazed to the spacing disks at the points where connection to the winding is desired.

Permanent contact pressure is maintained throughout the stack by stainless steel leaf springs at the ends of the stack. Both the spacing disks and the leaf springs are dimensioned so that they cannot protrude beyond the diameter of the Thyrite disks to produce concentrated voltage stress points which might endanger the insulation. The voltage stress at the ends of the stack is controlled by 1-inch thick contoured steel toroids designed to give optimum dielectric field conditions and insulated for maximum dielectric strength.

The rugged mechanical construction, simple electric connections, and effective insulation structure are illustrated in Fig. 5 which shows the application of Thyrite across the series winding of a 3-phase regulating autotransformer with load ratio control

Conclusions

1. The series windings of autotransformers present unusual surge voltage problems requiring special design attention.

2. Limiting the voltage across the terminals of the series winding with a by-passing rod gap or lightning arrester does not control the internal transient voltages in the winding.

3. Transient-voltage oscillations can be eliminated by shielding the winding to produce a linear surge-voltage distribution.

4. Thyrite provides an effective, safe, and practical means of obtaining linear voltage distribution.

◆

Discussion

W. A. Williams (General Electric Company, Pittsfield, Mass.): The author has demonstrated the effectiveness of Thyrite in the shielding of the series winding in an autotransformer. As pointed out, the use of such material gives the designer a means to reduce greatly the surge voltage to ground and to provide a linear distribution of voltage across the winding when the Thyrite is connected at regular intervals into the series winding.

The step voltage regulator is a particular type of autotransformer, and the same type of shielding is employed in this apparatus. In many of the step voltage regulator applications, the use of Thyrite is identical to that described in the paper. In such cases it is not designed to limit the voltage across the series winding but merely to insure that the distribution is linear.

However, many step voltage regulators in the lower voltage range, 15 kv and below, are of single-core construction. In these designs the taps are uniformly distributed across the series winding. On certain operating connections, near the tap changer neutral, 100 per cent of the surge voltage appearing between source and load bushings may appear across adjacent taps in the winding. Therefore, some means is desirable to limit the voltage. Connecting Thyrite across the active part of the winding is an effective way to limit this voltage. The voltage drop across the Thyrite is fixed by the characteristics of the material and the surge current it passes. Hence, the insulation between adjacent taps in the winding can be closely co-ordinated with the voltage drop across the Thyrite.

W. L. Teague and **L. B. Rademacher** (Westinghouse Electric Corporation, Sharon, Pa.): In Fig. 3 the author shows the voltage distribution that occurs in the series winding of an autotransformer for various terminal conditions. Figs. 3(A), 3(B), and 3(D) demonstrate that this particular winding has an extremely bad voltage distribution. Through better design of the series winding or by using shielding as the author suggests, the stress due to the voltage distribution may be reduced considerably. With an improved distribution, either a gap or a lightning arrester across the winding will prevent excessive voltages in the winding due to the oscillations.

Better distribution can be obtained by designing the series winding to have a high through capacitance relative to the ground capacitance or by using electrostatic shielding. In the core form transformer construction, this could be accomplished by using a Hisercap[1] or a Lowgrocap winding. By the interleaved-turns arrangement of the Hisercap winding, a high through capacitance is obtained. The Lowgrocap winding obtains the same result by decreasing the capacitance to ground through the use of static plates and winding arrangement. For shell form transformers, the windings inherently have a high through capacitance as compared to the ground capacitance. Thus by using either improved coil construction or shielding, the voltage distribution can be improved to reduce greatly the stresses that may occur when the series winding is protected with a gap or lightning arrester.

The design and protection of autotransformers is extremely complicated because of the voltages that may be induced internally due to the high volts per turn that develop from surges. The designer may use many schemes to prevent overstressing of the insulation. The winding may be designed to permit oscillations and sufficient insulation applied to withstand the overvoltages, or the design may be made to avoid excessive oscillations. Generally, the simplest and least hazardous method will prove to be the most reliable. By using the better voltage distribution approach, this problem is often simplified and complications are avoided.

Reference

1. Improved Core Form Transformer Winding, E. J. Grimmer, W. L. Teague. *AIEE Transactions*, vol. 70, pt. I, 1951, pp. 962–67.

J. W. Albright: I wish to express my appreciation to the discussers for their comments, which contribute substantially to the understanding of the problem. Mr. Williams has brought out an additional benefit which can be obtained from the application of Thyrite in some particular cases. In most high-voltage autotransformers the number of Thyrite disks required to shield the series winding is such that a voltage comparable to the basic insulation level will develop across the winding if current surges of 10,000 amperes or more are considered. However, in autotransformers where the operating voltage of the winding is very low compared to the basic insulation level, as in step voltage regulators, the volt-ampere characteristics of the Thyrite may limit the voltage to less than basic insulation level for surges of this magnitude. In these cases, the internal insulation of the winding can be safely co-ordinated with the voltage permitted by the Thyrite.

It is true, as Mr. Teague and Mr. Rademacher point out, that series winding transients can be reduced by means of electrostatic shielding. Electrostatic shielding has been used successfully for many years in transformers and in autotransformers with high coratio. Numerous varieties of electrostatic shielding have been developed in addition to the static plate for shell-type windings and the interlaced turn arrangement for the core-type disk windings mentioned by the discussers. Others in commercial use include rib shields for core-type disk windings, and cylindrical shileds for concentric laper windings.

Of these, only the cylindrical shields with concentric layer windings can be designed to produce essentially straight-line voltage distribution under all impulse conditions. All of the other varieties give varying results, depending upon the winding voltage and current rating, transformer or autotransformer rating, and wave shape of the surge applied to the terminals. The most difficult conditions are encountered in the series windings of autotransformers of low coratio. Here, the capacitance of the winding to ground is approximately the same as for a full capacity winding, but the series capacitance is very low because the number of turns in the winding is reduced to only a fraction of those in a full capacity winding. Since the proportions by which the ground capacitance can be reduced, and the series capacitance increased, by the electrostatic shields are about the same as in a full capacity winding, the ratio of ground capacitance to series capacitance is much higher in the series winding, and the internal voltage transients are correspondingly greater. Therefore, although the addition of electrostatic shields will improve the voltage distribution over that obtained without shields, the transient voltage oscillations are far from eliminated. Fig. 3(E) in the paper shows a winding with a very good initial voltage distribution produced by Thyrite interconnected at the mid-point of the winding, yet the maximum voltage between parts of the winding is three times the value obtained with essentially uniform voltage distribution in Fig. 3(C).

The voltage distribution of the winding used in the paper is extremely bad as stated by the discussers. However, it is also representative of the distribution obtained in any unshielded winding. The test results illustrated in Fig. 3 clearly demonstrate the ability of Thyrite, when interconnected to the winding at regular intervals, to produce essentially uniform voltage distribution in any winding without other aids.

Another advantage of Thyrite which makes it desirable for use in shielding is the simplicity of the application. The windings have normal turn distribution; it is not necessary to distort the turn distribution by interlacing, or to add capacitive elements in the critical dielectric field. Electrostatic shielding inevitably introduces complications in the windings and insulation. Furthermore, some types, such as static plates, occupy valuable space within the winding structure and increase the short-circuit reactance. Therefore, more active materials (copper and core iron) are necessary to maintain the transformer characteristics. These complications are avoided in those cases where Thyrite can be used, as in series windings of autotransformers.

Evaluation and Application of Silicone-Organic Resin Combinations for Dry-Type Transformer Insulation

G. F. SIMMONS
ASSOCIATE MEMBER AIEE

A. L. SCHEIDELER
ASSOCIATE MEMBER AIEE

THE rapid development of synthetic insulations in recent years has provided a challenge to the electrical designer. Incentives to utilize the improved mechanical and electrical properties of these new materials have been especially great in the design of apparatus operating in gaseous mediums. Dry-type transformers have provided a fruitful field for the application of such man-made materials.

Since transformers are designed for many years of life, it is necessary to resort to accelerated aging tests of insulation when determining its possible application. Results obtained with a specified set of laboratory procedures must then be extrapolated to the variety of operating conditions encountered in service. Recognition of this fact has resulted in considerable activity within the AIEE in an effort to establish standard conditions under which insulating systems may be evaluated. Such efforts have been in the direction of specifying material use as a result of functional tests rather than on the previous basis of chemical composition.

The inadequacy of chemical composition as a criterion in evaluating insulation has been well recognized. Perhaps, it is not so apparent that, in the present state of the science, chemical composition is likewise deficient as a basis for proposing insulation systems. Systems which may appear satisfactory for use when only chemical structure is considered are often found inadequate when subjected to the variety of conditions found in service. It is the purpose of this paper to demonstrate that insulation combinations which would not meet the arbitrary classifications based on organic content of the structure may prove not only satisfactory but superior when considered in the light of their function in a given piece of apparatus. The use of such combinations has resulted in an insulating system offering outstanding characteristics for dry-type transformers.

Composite Insulating Systems

The advantages of using silicone-based products in dry-type insulating systems are well known. They are characterized by stability at high operating temperatures and resistance to the absorption and harmful effects of moisture.[1–5,9] These advantages must be weighed against the difficulties which may arise in conjunction with silicone applications. The dielectric strength, mechanical strength, and curing characteristics for a given application are, in general, inferior to those of the best organic resins. High cost is also a limiting factor in many silicone applications.

To acquire the best of silicone characteristics as well as high dielectric and mechanical strength, it has been the practice to mix basic materials such as silicone and selected organic resins and use this mixture as a general-purpose resin. This practice has resulted in insulation structures with improved over-all properties, but which do not possess either the high degree of moisture resistance and life of

Paper 55-43, recommended by the AIEE Transformers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 19, 1954; made available for printing November 22, 1954.

G. F. SIMMONS and A. L. SCHEIDELER are with the General Electric Company, Pittsfield, Mass.

the silicones or the superior mechanical and electrical properties of the best organic resins.

It would obviously be very desirable to obtain a material or combination of materials which retain the good features of the best silicone and organic resins without accompanying limitations. If the functional requirements of constituents within a dry-type insulating system are considered, it may be seen that such a possibility exists.

The useful life of many insulating systems containing organic materials is greatly increased by the substitution of an inert material such as nitrogen for a circulating air atmosphere. Silicone-impregnated systems, while much superior to organic structures in air, are improved only slightly by the removal of oxygen from the surrounding medium.[6] Such evidence indicates that oxygen is a primary contributor to deterioration in dry-type apparatus and that the thermal superiority of the silicones stems largely from their resistance to the effect of oxygen. It may be inferred from these results that the silicones may, in proper combination, be used to extend the life of certain organic materials.

This investigation was conducted in an effort to develop a dry-type transformer insulating system which would utilize the high dielectric and mechanical strength characteristics of selected, organic impregnants and the temperature- and moisture-resisting characteristics of suitable silicones. It was desired to accomplish this in as economical a manner as possible by using a minimum of silicone resin.

Emphasis was placed on the use of silicone resins as a surface treatment of conventional 150-degree-centigrade (C) base insulations. By this procedure, the silicone replaced the weakest link in the present 150-C system, the organic impregnating varnish. The organic constituent of the base material was shielded by the silicone resin coating from the deteriorating effects of oxygen and moisture.

Evaluation of Pertinent Properties

Two criteria[8] have been utilized in determining the aging performance of the materials under study. These are the dielectric strength at the elevated aging temperature and the power factor after exposure of the insulating component to high humidity.

Dielectric Breakdown

When a component insulation system is not subjected to an undue amount of moisture or mechanical abuse, the dry dielectric strength of the component becomes the predominating factor in determining insulation life. Such conditions will be present when the apparatus is operating in a clean, dry enclosure or when a sealed type of construction is used and maintained. Reduction of dry dielectric strength may be utilized then to estimate a reasonable maximum life for the material.

The per-cent reduction in dielectric strength which should be chosen as a criterion for end of life depends on the application and system under consideration. The manner in which a component insulation approaches failure may be just as important to the designer as the failure point. A desirable procedure is to define life as a function of the per cent of initial dielectric strength which is chosen as the failure point.

The large number of samples and amount of testing required rule out this method in many instances. A 50-per-cent criterion has been widely used as meeting most requirements for transformer applications, the implication being that a 50-per-cent reduction in dielectric strength in a transformer, as designed, will result in marginal operating conditions. The data herein are treated in terms of a 50-per-cent criterion where the time to failure at 50 per cent of initial breakdown levels has been determined. No such reduction has been observed with some of the materials considered during long periods at elevated temperatures. Those data have been analyzed in terms of desired operating temperatures.

Power Factor

The minimum life of insulation used in ventilated dry-type transformers is determined essentially by the moisture-resisting properties of the composite insulation. When the material has deteriorated because of thermal aging, by flaking, crazing or charring, it no longer provides either the mechanical bonding or the moisture resistance necessary for operation under adverse conditions. Hence, deterioration in resistance to the effects of moisture as measured by power factor on a humidified sample is a comparatively simple, but comprehensive, test for defining the minimum life of a composite dry-type transformer insulation. Resistance-to-moisture absorption may also be used to define the optimum curing characteristics of a material, provided dielectric and mechanical properties are adequate.

Construction of Component Samples

The component samples were, in instance, designed to provide a reasonable representation of the conditions to which the materials would be subjected in a transformer. The completed structures are shown in Fig. 1.

Turn Insulation

The turn insulations investigated were applied to rectangular copper wire, using

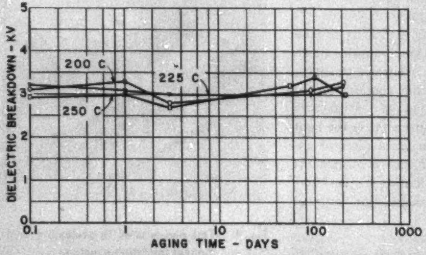

Fig. 2. Turn insulation dielectric breakdown of a silicone resin impregnated asbestos sheet and glass yarn, bonded and treated with silicone. For power-factor data see Fig. 3

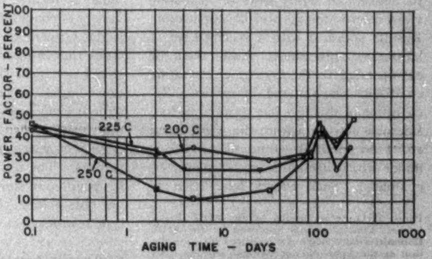

Fig. 3. Turn insulation power factor at 90-per-cent relative humidity of a silicone resin impregnated asbestos sheet and glass yarn, treated and bonded with silicone. For breakdown data see Fig. 2

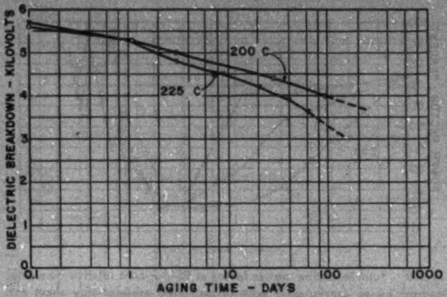

Fig. 4. Turn insulation dielectric breakdown of an acrylic ester resin impregnated asbestos sheet and glass yarn, phenolic resin treated. For power-factor data see Fig. 5

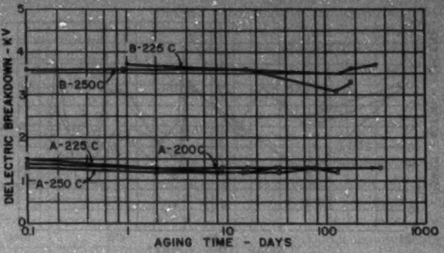

Fig. 6. Turn insulation dielectric breakdown of (A) a phenolic resin bonded glass yarn treated with silicone and (B) an acrylic ester resin impregnated asbestos-clay sheet and glass yarn, bonded and treated with silicone. For power-factor data see Figs. 8 and 9

standard factory processes.[6] The insulated wire was cut into 10-inch lengths. Two pieces were placed together in a jig and a 2-inch length on each end of the sample was spread apart. The middle 6 inches were then tied together with glass yarn and the completed samples were given a standard factory treatment with the desired varnish. The electrodes used in testing the insulation were the two copper wires.

LAYER INSULATION

The insulating material being investigated was wound on a metal mandrel after the manner of Whitman and Stewart.[7] Sheet material of desired thickness was wrapped around a metal mandrel with a 2-inch outside diameter and 18 inches long. Tinned copper electrodes 1/2 inch wide and positioned 2 inches apart were wrapped around the insulation and held in place by means of copper binding wires. The sample was then given a factory treatment with the desired varnish.

BARRIER INSULATION

Small cylinders (approximately 6 inches in diameter and of appropriate thickness) were wound with the desired materials using factory operating procedures. The completed cylinder was then given a factory treatment with the desired varnish.

Interpretation of Results

TURN INSULATION

It is apparent from the typical results illustrated in Fig. 2 that high-temperature turn insulations, utilizing silicones as the resinous constituents, possess very stable dielectric strength characteristics as a function of time and temperature. Even though long testing times were involved, the dielectric strength was not reduced. A life of 20,000 hours at the hottest spot temperature has been recommended as a criterion of minimum life for a dry-type transformer insulating system.[7] When established slopes[8,9] of life versus temperature for silicone insulated systems are considered, it becomes apparent that, on a dielectric strength basis, these components are suitable for operation at temperatures well above 200 C. It may well be that other factors, i.e., copper oxidation rather than insulation life may impose the temperature limit in silicone-insulated apparatus.

The impregnating resin must also perform the very important function of inhibiting the entrance of moisture into the system during that part of the apparatus load cycle which results in low insulation temperatures. Silicone-impregnated and treated components are, after exposure to 250 C for more than 200 days, as resistant as new materials to moisture effects measured by power factor; see Fig. 3. Actually, aging at high temperature improves the moisture-resisting properties for a considerable period.

Comparable, high-temperature turn insulation containing an organic impregnant and treated with an organic varnish[6] has been analyzed on the basis of a 50-per-cent dielectric strength criterion. These data have been reproduced in Fig. 4. On the basis of results extrapolated from

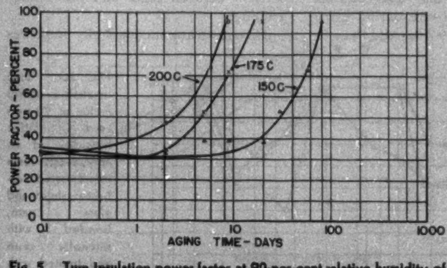

Fig. 5. Turn insulation power factor at 90-per-cent relative humidity of an acrylic ester resin impregnated asbestos sheet and glass yarn, phenolic resin treated. For breakdown data see Fig. 4

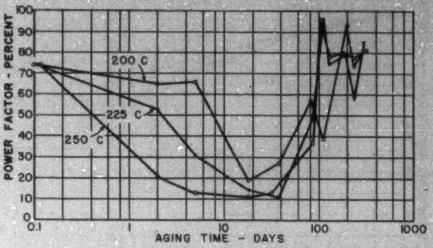

Fig. 9. Turn insulation power factor at 90-per-cent relative humidity, comprising an acrylic ester resin impregnated asbestos-clay sheet and glass yarn, bonded and treated with silicone. For breakdown data see Fig. 6

Fig. 4, the composite insulation is limited under these maximum life conditions to an operating temperature of approximately 170 C. A somewhat higher maximum operating temperature may be calculated if a less than 50-per-cent criterion is utilized.

The weakest link in this system, however, is the organic, final treating varnish, Fig. 5 reproduced from reference 6 illustrates that such a high-temperature, phenolic-varnish-treated turn insulation will not maintain its resistance to the effects of moisture throughout the minimum required life at 150 C. This is true in spite of the fact that the varnish under consideration is superior to most other organic varnishes in maintaining its properties as a function of time and temperature.

When silicone resin is substituted for the organic-treating varnish, the resulting composite exhibits dielectric strength characteristics as a function of time and temperature which are very similar to those of the comparable system where all resins are silicones. The dielectric strength versus aging times characteristics, illustrated in Figs. 6 and 7, demonstrate that the composite turn insulations containing organic constituents in the base material will more than meet accepted criterion for operation at hottest spot temperatures of 200 to 220 C after treatment with silicone resins.

The resultant composite possesses moisture-resisting characteristics which approach those of conventional systems designed for 200 to 220 C of hottest spot temperatures. Although there are occasional anomalous fluctuations in the power factor after humidification, the structures still function as effective moisture barriers after a year at 250 C; see Figs. 8, 9, and 10. It may be seen from a comparison of Figs. 9 and 10 that the use of a phenolic resin binder for the glass yarn has a measurably adverse effect on moisture-resisting properties. The phenolic resin is superior, however, to a silicone bonding resin in preventing fraying of the glass fibers both before and during aging.

Layer Insulation

Mica paper impregnated with a high-temperature polyester resin possesses dielectric strength and loss characteristics which make it very desirable for use as layer insulation and as electric padding for major insulation, i.e., barriers, in dry-type transformers. Its comparatively weak mechanical characteristics limit its use at present to applications where the material may be used in sheet form. As a consequence, it was evaluated as layer insulation. When treated with silicones, the material will perform adequately at hottest spot temperatures approaching 200 C. The life at 20,000 hours on the basis of a 50-per-cent dielectric strength criterion is at least 190 C; see Fig. 11. Its aging characteristics are very similar to those of silicone-impregnated asbestos in an air atmosphere.

The composite is also very resistant to the effects of moisture and thermal cycling. Weekly exposure during aging to an atmosphere at 90 degrees Fahrenheit of 90-per-cent relative humidity for 24 hours followed by 24 hours at room conditions resulted in approximately a 45-per-cent reduction in life on the basis of a 50-per-cent dielectric strength criterion. Although no comparative data are available, it is believed that such a reduction is small when the severe cycling is considered.

Major Insulation

The data available indicate that a 150-C major insulation is much improved by the use of a silicone treatment. Many 150-C insulation structures so treated give satisfactory operation in apparatus with hottest spot temperatures of over 200 C.

Improvements in insulation functioning brought about by this treatment are not confined to a specific base material or resin-base material combination. The merits of the final silicone treatment are apparent even with an essentially inorganic insulating structure. One insulation of the inorganic type which is an economical material based on the discovery of a controllable phospho-asbestos reaction may be formed as cylinders for barriers between high- and low-voltage windings.

Silicone treatment markedly improves

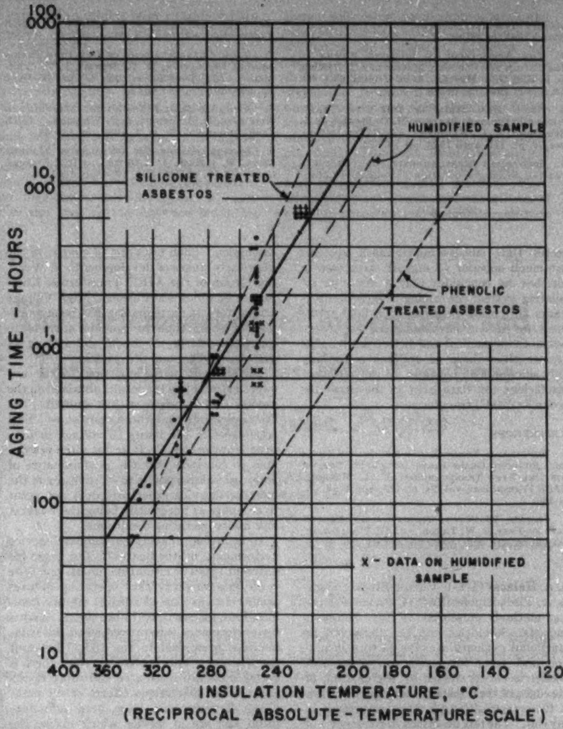

Fig. 11. Aging characteristics utilizing 50-per-cent initial dielectric strength criterion. Layer insulation is a polyester resin impregnated mica paper sheet treated with silicone. Curves for silicone-treated and phenolic-treated asbestos from reference 5

the initial dielectric properties and moisture resistance of this structure. Prolonged exposure to aging temperatures as high as 250 C are actually beneficial to its dielectric properties. The effect of thermal aging on the dielectric strength and moisture resistance of such cylinders treated with silicone are illustrated in Figs. 12 and 13. All of the composite structures, turn, layer, and barrier, remained mechanically sound throughout the aging periods. Their appearance, as aging progressed, resembled that of systems containing only silicone impregnants.

Conclusions

The results of this investigation demonstrate once more the inadequacy of existing "class" designations for high-temperature insulation. A better procedure is to consider the functional requirements of each basic material in a component insulation. Then, by proper selection, materials of different classes may be used in combination to produce superior insulating systems for many applications.

The consequences of this approach to the design of dry-type transformer insulating systems have been especially significant. It is possible to utilize the outstanding dielectric and mechanical strength characteristics of selected organic impregnants and the temperature- and moisture-resisting characteristics of good silicones. This may be accomplished in an economical manner while using a minimum of silicone.

A dry-type insulating system containing organic impregnants and using silicones as a final treatment offers the following advantages for use in circulating air apparatus.

1. The thermal stability of the system is adequate for operation at hottest spot temperatures geater than 200 C.
2. The resistance of the system to moisture is maintained throughout transformer life and is much greater than that of the usual 150 C system.
3. The insulating components will, in general, possess mechanical and dielectric strengths greater than those of systems containing only silicone impregnants.
4. The versatility and areas of dry-type transformer applications are greatly increased by the use of this insulating structure.

◆

Discussion

M. L. Manning (Pennsylvania Transformer Company, Canonsburg, Pa.): This paper makes a plea for silicone-organic resins for dry-type transformer application. Most tests were conducted on a component basis in what is called a "reasonable representation" of the conditions to which materials would be subjected in a transformer. I am not sure after reading the paper whether ventilated or sealed construction is advocated in transformers for use of these resins. Emphasis is placed on the use of silicone resins as a surface treatment of conventional 150 C base insulations. In other words, the organic link in the base material is shielded from the effects of oxygen and moisture by the silicone resin coating. To back the author's plea for what might be called "the foster relatives of the silicone family," the organic resins do not possess the life of the silicone resins.

To clarify the situation for usage in transformers, I suggest the following procedure:

1. A direct comparison should be made with 15-kv class transformer models aged in air.[1] This comparison would be made using the same tests including power factor of major insulation and same construction of models. Such a structure actually simulates a power transformer, i.e., pancake high-voltage coils, axial spacers, and barrier insulation.
2. A direct comparison should be made with transformers in service. Mention is not made of the service performance of transformers utilizing the silicone-organic resins.
3. What happens if a short-circuit failure occurs in the silicone-organic-insulated transformers? By test, sealed silicone-insulated transformers have been proved safe through 600 C temperature.[2] Combustion is not supported.
4. If nitrogen atmosphere is lost, what happens to organic-silicone resins used at 220 C temperature in air, the present hottest spot temperature permitted for group 3 dry-type transformers in air? Silicone resins and rubbers used in the insulation structure described in reference 1 make use of the high heat-stable silicones. This insulation system can be used at 220 C in air. From the users' point of view, it would seem that security is desired in the ability of a transformer to carry normal load in event of nitrogen leakage.

The statement that "silicone-impregnated systems... are improved only slightly by the removal of oxygen from the surrounding medium" is contradictory to data submitted in reference 5 of the paper. The author states that silicone-impregnated systems are much superior to organic structures in air, but he concludes that a dry-type insulating system containing organic impregnants and using silicones as a final treatment for use in circulating air apparatus possesses mechanical and dielectric strengths greater than those of systems containing only silicone impregnants. It appears that insufficient test data exist in the paper for group 3 (220 C) transformers.

A. A. Halacsy (I-T-E Circuit Breaker Company, Philadelphia, Pa.): I question if the test methods presented by Mr. Simmons and Mr. Scheideler can be considered as functional evaluation as far as turn insulation and layer insulation are concerned. Dielectric effects caused by the crossing of the edges of the adjacent wires will not show in these tests although they are present in any coil. The test described in reference 1 of M. L. Manning's discussion is certainly a better functional evaluation and should result in lower breakdown voltages. Have the authors made any comparative tests justifying their simplification?

The tests showed that creepage sets the limit to the voltage in dry-type transformers. Do the authors think it possible and practical to build dry-type transformers for voltages higher than the 15-kv class in the light of the difficulties experienced in creepage?

G. F. Simmons and **A. L. Scheideler**: Dr. Halacsy has questioned the functionality of the test samples used for layer and turn insulation tests. It must be remembered that the primary purpose of these tests is to assess the thermal stability of the system and not to evaluate dielectric breakdown levels of a complete transformer. The samples are satisfactory for determining thermal stability since they are being subjected to fields typical of those in the bulk of the transformer coil. Crossovers are further removed from consideration since in general they are insulated in addition to the insulation provided by the regular wire covering.

Both Mr. Manning and Dr. Halacsy have suggested that these insulation combinations be tested by the use of models aged in air, as described in reference 1 of Mr. Manning's discussion. Such tests are, of course, in the very early stages of development. A Working Group of the AIEE Transformer Committee in which the Pittsfield High Voltage Laboratory is participating has been working for some time to provide answers to questions relating to model size and structure, test cycles, and life criteria.

An example of the questions to be answered is raised by the results obtained on the models in the reference just quoted. Dr. Halacsy states that those tests show "that creepage sets the limits to voltage in dry-type transformers." It seems more reasonable to conclude that the predominance of creepage failures points to a deficiency in the models. Service experience does not point to creepage as necessarily being the weakest link under operating conditions.

It is rather difficult to compare service performance on the basis of a few years for different types of insulation, unless one type is so unsatisfactory that operating failures occur. In the case of silicone-organic combinations, as described in the paper, operating performance is improved when this combination is applied to the 150 C hot-spot transformer. This is obvious, since there is better moisture resistance and more resistance to the deleterious effects of temperature. Transformers have been manufactured and are in service which utilize the silicone-organic combination.

Suitable silicone-organic resin combinations, as described in this paper, are dependable for use at 220 C hot-spot temperatures, either in air or in nitrogen. It is advocated that open dry-type transformers for use at temperatures of 220 C hot spot embody these combinations. Obviously, if these insulations are good for use in air, there is no problem in the sealed dry-type transformer if air should perchance replace the nitrogen, except as to the moisture effects upon unpainted steel surfaces and the like.

It has been shown[1] that the decomposition products of even silicone insulated systems are combustible. Combustion was not supported during the short-circuit failure referred to in Mr. Manning's reference 2 because the coil was immersed in nitrogen. We would suggest that criteria for flammability of a transformer coil structure be related to the total organic and semiorganic (i.e., silicone) content of the structure.

The mechanical strength of the coil is of prime importance in preventing short-circuit failures. The silicone-organic resin combinations described in the paper embody the superior mechanical strength as well as excellent high temperature life. The organics in such combinations do not soften as do existing silicones at the high temperatures encountered during either overload or short circuit. The composite may therefore be expected to exhibit more reliability than can be obtained in presently available silicone systems.

Mr. Manning questions our statement that silicone-impregnated systems are improved only slightly by the removal of oxygen from the surrounding medium. Although the improvement is significant, it is much less than that obtained with organic resins. It is true that silicone-impregnated systems are much superior to organic structures in air from both the moisture-resistant and high-temperature-life point of view. It is also true that a dry-type insulating system containing organic impregnants, and using silicones as a final treatment for use in circulating air apparatus, possesses, mechanical and dielectric strengths greater than those of systems containing only silicone impregnants. Nothing is contradictory about the two statements since they refer to different properties. We agree that the use of silicones overcoating organic resins would not result in a better moisture-resistant and high-temperature-life condition than with pure silicone-impregnated systems. However electric and mechanical strength are of as great importance as moisture resistance and high temperature life in electric apparatus.

Dr. Halacsy questions the practically of dry-type transformers for voltages higher than the 15-kv class. Such a unit, which is now being manufactured, utilizes a gas with a higher dielectric strength than nitrogen, thus improving all insulation characteristics.

The Determination of Incremental and Total Loss Formulas from Functions of Voltage Phase Angles

C. R. CAHN
ASSOCIATE MEMBER AIEE

A NEW approach in the form of remarkably simple formulas for the determination of incremental transmission losses in electric power systems has been advanced by Brownlee.[1] He derived the formulas for the simplest possible transmission system of two generators connected by a single transmission line and apparently showed them to be applicable to practical power systems by heuristic reasoning, which lead him to solve some numerical cases. Brownlee's formulas are functions of the phase angles of the generator bus voltages, so that their application is restricted to those cases where the phase angles are known. Since phase angles are not presently available on the actual system, Brownlee's results are useful at this time mainly in load studies on a-c network analyzers.

The purpose of this paper is to provide a more solid foundation for Brownlee's results, showing some of the conditions which must be satisfied for their validity, to provide additional numerical examples of the successful use of Brownlee's theory, and to provide an extension of Brownlee's theory to give expressions for incremental and total losses which do not require knowledge of generator voltage phase angles. The resulting loss formulas are conventional in that they require specification of the generator power outputs only. It is believed, however, that the method of calculating incremental and total loss formulas presented here is considerably simpler than any yet advanced.

The Brownlee Formulas

The Brownlee formulas in slightly modified form are derived and presented here for reference. The sending end and receiving end power inputs to a transmission line of impedance $Z=R+jX$ are

$$P_1=\frac{V_1^2R}{R^2+X^2}-\frac{V_1V_2}{R^2+X^2}(R\cos\theta-X\sin\theta) \tag{1}$$

$$P_2=\frac{V_2^2R}{R^2+X^2}-\frac{V_1V_2}{R^2+X^2}(R\cos\theta+X\sin\theta) \tag{2}$$

where θ is the angle by which the sending end voltage leads the receiving end. The subscripts 1 and 2 denote the sending end and the receiving end respectively. If it is assumed that the two ends are maintained at constant voltage, any change in P_1 and P_2 is caused by a variation in θ. Differentiating with respect to θ and defining the transmitted power as the average of the sending end and receiving end powers results in

$$dP_L/d\theta=\frac{2V_1V_2}{R^2+X^2}R\sin\theta \tag{3}$$

$$dP_{1-2}/d\theta=\frac{V_1V_2}{R^2+X^2}X\cos\theta \tag{4}$$

$$dP_L/dP_{1-2}=2\frac{R}{X}\tan\theta \tag{5}$$

where $P_L=P_1+P_2$ is the system loss and $P_{1-2}=(1/2)(P_1-P_2)$ is the transmitted power. Integrating with respect to θ between the initial value θ_a and the final value θ_b, the equations for a finite change are obtained

$$\Delta P_L=\frac{4V_1V_2}{R^2+X^2}R\sin\left(\frac{\theta_b+\theta_a}{2}\right)\sin\left(\frac{\theta_b-\theta_a}{2}\right) \tag{6}$$

$$\Delta P_{1-2}=\frac{2V_1V_2}{R^2+X^2}X\cos\left(\frac{\theta_b+\theta_a}{2}\right)\sin\left(\frac{\theta_b-\theta_a}{2}\right) \tag{7}$$

$$\Delta P_L/\Delta P_{1-2}=2\frac{R}{X}\tan\left(\frac{\theta_b+\theta_a}{2}\right) \tag{8}$$

In the foregoing derivation the variations caused by changes in voltage magnitude have been neglected completely. This is justified by the actual practice on power systems of maintaining all busses at practically constant voltage. Thus, although a 1-degree change in the phase angle between two plants is quite small, it produces as much voltage acting to circulate current as a 2-per-cent change in the voltage magnitude at one of the plants, a quite considerable voltage change. Therefore, it is assumed in the following that voltage magnitude variations never need to be taken into account.

Paper 55-25, recommended by the AIEE System Engineering Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing November 15, 1954.

C. R. CAHN is with Syracuse University, Syracuse, N. Y.

The author wishes to thank H. L. Harrington, H. B. Smith, W. D. Wilder and other members of the Niagara Mohawk Power Corporation, Buffalo, New York, for their advice and support. Particularly invaluable during the development of the theory was the counsel, both technical and otherwise, of D. W. Spence, Supervisor of the Network Analyzer Laboratory at Syracuse University, who also supplied extensive personal efforts towards the obtaining of the network analyzer data. Some of the calculations were made by D. D. Nadkarni.

The material contained in this paper was adapted from a portion of a dissertation submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy at Syracuse University, Syracuse, New York.

The Brownlee Formulas on Practical Systems

The demonstration of the applicability of the Brownlee formulas to practical systems hinges on the finding of an analytical method of exchanging generation between two plants or tie lines, all of which will be called "generators." One possibility is to take advantage of the fact that a considerable variation in the power flows has only a relatively small effect on the voltages at the loads if the generator voltages are held fixed. Then, if one generator has its voltage phase angle increased at constant magnitude, holding the voltage of another generator fixed in both magnitude and angle and holding the currents of all other generators and of all loads fixed in both magnitude and angle, the result will be an approximation to the desired condition where generation is exchanged between the two generators with no other changes in the generation or in the loads. The low impedance of the transmission system connecting the two generators allows a large change in their currents with only small voltage changes on the system. Changes in power at the other generators and at the loads are a result of the small voltage changes acting on a fixed current. If the other generators and loads were then trimmed to their proper values, the additional incremental losses would be small in comparison with those caused by the major swing.

The procedure just described for exchanging generation between two generators will now be applied to a transmission system with three points of entry, the first two being the aforementioned two generators, the third being an additional generator or load, as shown in Fig. 1. This is the most general system which must be considered since the extension to a larger number of points of entry will be evident. The results to be obtained will indicate some of the conditions which must be satisfied for the validity of Brownlee's formulas on practical systems.

The system is isolated from ground except at the points of entry, with the usual assumptions of neglecting off-nominal turns-ratios and lumping line charging in the loads being made. In terms of the open-circuit self- and mutual impedances Z_{nm} with generator 2 grounded, the relations between voltages and currents are

$$\begin{aligned} E_1-E_2&=Z_{11}I_1+Z_{13}I_3\\ E_3-E_2&=Z_{31}I_1+Z_{33}I_3 \end{aligned} \qquad (9)$$

where I_2 does not appear in the equations.[2,3]

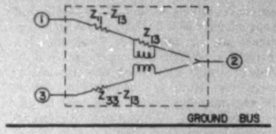

Fig. 1. Transmission system equivalent

In addition, the current I_2 is the negative of all other currents combined. That is

$$I_2=-I_1-I_3 \qquad (10)$$

Solving equations 9 and 10 for I_1 and I_2 gives

$$\begin{aligned} I_1&=\frac{1}{Z_{11}}(E_1-E_2)-\frac{Z_{13}}{Z_{11}}I_3\\ I_2&=\frac{1}{Z_{11}}(E_2-E_1)-\left(1-\frac{Z_{13}}{Z_{11}}\right)I_3 \end{aligned} \qquad (11)$$

If equations 11 are multiplied by the complex conjugate voltages E_1^* and E_2^* respectively, and the second equation 9 is multiplied by I_3^*, the complex power inputs to the three points of entry are found to be

$$W_1^*=E_1^*I_1=\frac{1}{Z_{11}}(E_1E_1^*-E_1^*E_2)-\frac{Z_{13}}{Z_{11}}E_1^*I_3$$

$$W_2^*=E_2^*I_2=\frac{1}{Z_{11}}(E_2E_2^*-E_1E_2^*)-\left(1-\frac{Z_{13}}{Z_{11}}\right)E_2^*I_3 \qquad (12)$$

$$W_3=E_3I_3^*=E_2I_3^*+Z_{31}I_3^*I_1+Z_{33}I_3^*I_3$$

Differentiating with respect to the angle of θ_1, assuming that the magnitude of E_1 and all other quantities are fixed and taking the real part to get only the real power loss, gives

$$dP_1/d\theta_1=\frac{V_1V_2}{|Z_{11}|^2}[R_{11}\sin(\theta_1-\theta_2)+X_{11}\cos(\theta_1-\theta_2)]+\left(Re\frac{Z_{13}}{Z_{11}}\right)V_1|I_3|\times\sin(\theta_1-\phi_3)-\left(Im\frac{Z_{13}}{Z_{11}}\right)V_1|I_3|\times\cos(\theta_1-\phi_3) \qquad (13)$$

$$dP_2/d\theta_1=\frac{V_1V_2}{|Z_{11}|^2}[R_{11}\sin(\theta_1-\theta_2)-X_{11}\cos(\theta_1-\theta_2)] \qquad (14)$$

$$dP_3/d\theta_1=-\left(Re\frac{Z_{31}}{Z_{11}}\right)V_1|I_3|\sin(\theta_1-\phi_3)-\left(Im\frac{Z_{31}}{Z_{11}}\right)V_1|I_3|\cos(\theta_1-\phi_3) \qquad (15)$$

where $E_n=V_n\underline{/\theta_n}$ and $I_n=|I_n|\underline{/\theta_n}$. *Re* and *Im* mean real part and imaginary part respectively. Then the rates of change of power loss and transmitted power with θ_1 are

$$dP_L/d\theta_1=\left(\frac{dP_1}{d\theta_1}+\frac{dP_2}{d\theta_1}+\frac{dP_3}{d\theta_1}\right)=\frac{2V_1V_2}{R_{11}^2+X_{11}^2}\times R_{11}\sin(\theta_1-\theta_2)+2V_1|I_3|\cos(\theta_1-\phi_3)\times\frac{R_{13}X_{11}-X_{13}R_{11}}{R_{11}^2+X_{11}^2} \qquad (16)$$

$$dP_{1-2}/d\theta_1=1/2\left(\frac{dP_1}{d\theta_1}-\frac{dP_2}{d\theta_1}\right)=\frac{V_1V_2}{R_{11}^2+X_{11}^2}\times X_{11}\cos(\theta_1-\theta_2)+1/2V_1|I_3|\sin(\theta_1-\phi_3)\times\frac{R_{13}R_{11}+X_{13}X_{11}}{R_{11}^2+X_{11}^2}+1/2V_1|I_3|\times\cos(\theta_1-\phi_3)\frac{R_{13}X_{11}-X_{13}R_{11}}{R_{11}^2+X_{11}^2} \qquad (17)$$

It is seen that equations 16 and 17 are the same as equations 3 and 4 with additional correction terms. However, the correction terms in practical cases may be expected to be small for two reasons. The first is that the magnitude of a load or generator current is normally small in comparison with the ratio of the system voltage to the self-impedance of a generator (with another generator grounded) unless large loads are supplied by large generations in the same area. The second is that the correction term in equation 16 is zero if the resistance-reactance ratio is uniform in the system. It may be expected that the resistance-reactance ratio of the self- and mutual impedances will not vary excessively for most loop interconnected systems unless there exists important transmission at different voltage levels. The first correction term in equation 17 is small for high power-factor loads, and the major cosine term is large enough so that the correction terms in this equation can be disregarded in all practical cases. Since the major term of equation 16 involves a sine of a small angle, it may be expected that the incremental losses will be more in error than the incremental transmitted power when the correction terms are neglected.

It is thus clear why the Brownlee formulas can work on practical systems. Since all other points of entry to the system besides those of the two generators between which generation is exchanged are considered as open circuits during the swing, the proper impedance to use in Brownlee's formula is the one measured with all loads and capacitors disconnected. A final verification is provided by numerical examples presented in the following.

A New Derivation of Incremental Loss Coefficients

The Brownlee formulas, having been shown suitable for application to most practical power systems, are used as the point of departure in the development of expressions more suitable to economic studies. Since phase angles are not available on present-day power systems, they cannot be used in system operation without the introduction of additional telemetering equipment, which must be highly accurate because of the small phase-angle differences involved. Also, phase angles could not be of use in economic scheduling of generation, since they could not be accurately predicted. Thus, expressions involving powers are preferable except for system planning on a network analyzer where phase angles are available. Such expressions may be obtained if it is possible to relate phase angles to generator powers. The relationship may be established from the first equation 9. The left side of the equation can be manipulated so that it becomes proportional to the major term on the right side of equation 16, while the right side of equation 9 can be manipulated into the form of the sum of terms, each of which is a coefficient times a generator or a load power.

Then, provided that the correction terms in equations 16 and 17 can be neglected, it is shown in Appendix I that the incremental loss between generators n and M is given by

$$dP_L/dP_{n-M}=\sum_{m=1}^{N} A_{nm}P_m \qquad (18)$$

where P_m is the power output of generator m, P_{n-M} is the average of P_n and $-P_M$ and a total of N generators numbered 1 to N is assumed. There are $N-1$ equations, one for each value of $n\neq M$. For $n=M$ all coefficients are zero. The A_{nm} coefficients are taken as constants evaluated from a chosen base case. As originally derived, the sum in equation 18 was extended over all generators except number M and over all loads. However, the load powers were eliminated and the output of generator M was introduced by using the approximation that the total generation equals the total load, neglecting the effect of losses as a second-order correction. Also required to eliminate the loads were the assumptions that each load power remains a fixed fraction of the total load and that the Q/P ratio of each load remains fixed. Line charging is included in the loads. The A_{nm} coefficients will be called incremental loss coefficients.

The A_{nm} coefficients are evaluated by the following procedure:

1. Select a large generator to be the swing machine M and, with its point of entry grounded, measure the open-circuit self- and mutual resistances and reactances R_{nm} and X_{nm} between the generators. A procedure for making these measurements on the network analyzer is described in the literature.[3]

2. Using values from the base case, calculate for each value of n and m

$$D_{nm}=2K_{nm}X_{nm}\times \frac{(1-s_mK_{nm})\cos(\theta_m-\theta_n)+(s_m+K_{nm})\sin(\theta_m-\theta_n)}{V_nV_M\cos(\theta_n-\theta_M)} \qquad (19)$$

where $K_{nm}=R_{nm}/X_{nm}$ and $s_m=Q_m/P_m$ is the ratio of the reactive output to power output of generator m.

3. Calculate for each n

$$(dP_L/dP_{n-M})_{\text{base case}}=2K_{nm}\times \tan(\theta_n-\theta_M)_{\text{base case}} \qquad (20)$$

4. Using the base case generator powers, calculate for each n

$$w_n=\frac{\sum_{m=1}^{N} D_{nm}P_m-(dP_L/dP_{n-M})_{\text{base case}}}{\sum_{m=1}^{N} P_m} \qquad (21)$$

5. Calculate for each value of n and m

$$A_{nm}=D_{nm}-w_n \qquad (22)$$

It has been found that greater accuracy is obtained if the portions of the reactive outputs which do not vary with exchanges of generation are included with the loads before calculating the generator Q/P ratios. In lieu of such data it is suggested that each s_m be taken as equal to either zero or its base case value, whichever is algebraically smaller.

Equation 18 may be used for finite increments also if average powers are used. From equations 5 and 8, rewritten for exchanging generation between plant n and plant M, and equation 18

$$\begin{aligned}\Delta P_L/\Delta P_{n-M}&=2K_{nn}\tan(\theta_n-\theta_M)_{\text{av}}\\&=2K_{nn}\tan\frac{(\theta_n-\theta_M)_{\text{initial}}+(\theta_n-\theta_M)_{\text{final}}}{2}\\&\approx 1/2[2K_{nn}\tan(\theta_n-\theta_M)_{\text{initial}}+2K_{nn}\tan(\theta_n-\theta_M)_{\text{final}}]=\sum_{m=1}^{N}A_{nm}(P_m)_{\text{av}}\end{aligned} \qquad (23)$$

This development assumes that the phase-angle differences are all small, as must be the case if the derivation of equation 18 is to be valid.

The application of equation 5 or 18 to the economic scheduling of generation is now outlined. At the most economic dispatch, generation may be exchanged between two plants without affecting the fuel cost input. Letting F_n be the fuel cost input of plant n, for each $n\neq M$

$$dF_n+dF_M=0 \qquad (24)$$

or

$$\frac{dF_n}{dP_n}(dP_{n-M}+1/2dP_L)=-\frac{dF_M}{dP_M}(-dP_{n-M}+1/2dP_L) \qquad (25)$$

Rearranging equation 25 gives

$$\frac{dF_n}{dP_n}\,\frac{1+(1/2)dP_L/dP_{n-M}}{1-(1/2)dP_L/dP_{n-M}}=\frac{dF_M}{dP_M} \qquad (26)$$

To a reasonable degree of approximation it may be written that

$$\frac{1+(1/2)dP_L/dP_{n-M}}{1-(1/2)dP_L/dP_{n-M}}\approx 1+dP_L/dP_{n-M}\approx\frac{1}{1-dP_L/dP_{n-M}} \qquad (27)$$

since dP_L/dP_{n-M} is normally relatively small. It may be shown that incremental loss coefficients can be applied in the same manner as total loss coefficients except in the calculation of total losses.

Derivation of Total Loss Coefficients from Incremental Loss Coefficients

The preceding incremental loss formula, equation 18, is entirely satisfactory for economic scheduling of generation and becomes inadequate only when total losses are desired, as is the case if an evaluation of annual fuel cost savings is to be made. For such purposes the derivation of a total loss formula is necessary. It is shown in Appendix II that a total loss formula of the form

$$P_L=\sum_{n=1}^{N}\sum_{m=1}^{N}P_nB_{nm}P_m \qquad (28)$$

can be derived from the incremental loss formula of equation 18. The assumption is made in the derivation that the total loss is proportional to the square of the total generation when all loads and all generations are changed proportionately. This is reasonable if the busses are maintained at nearly constant voltages. The derivation calculates the total loss for an arbitrary generation total by first multiplying all generator powers in the base case by the ratio of the actual total generation to the base case total generation. Then, starting from the scaled base case and maintaining the total generation constant, each generator in turn is changed from its scaled base case output to its value in the actual case, the incremental loss caused by the change being calculated by equation 18. The various calculated increments are added to the scaled power loss of the scaled base case to get the total loss of the actual case. The result is then rearranged in the form of equation 28.

Table I. Generation Data

Table II. Base Case Data

n	V_n	θ_n	s_n
1	1.015	8.0°	−0.200
2	0.980	8.0°	−0.560
3	0.953	22.1°	−0.210

The procedure for calculating the B_{nm} coefficients from the A_{nm} coefficients is now outlined:

1. For each value of n, using the generator powers from the base case, calculate

$$a_n = \frac{\sum_{m=1}^{n} A_{nM}P_m + \sum_{m=n+1}^{N} (A_{nm}-A_{mn}+A_{mM})P_m}{2\sum_{m=1}^{N} P_m} \tag{29}$$

2. Calculate for each value of n and m with $n \geqq m$

$$\mathbf{B}_{nm} = \mathbf{B}_{mn} = (1/2)(A_{nm}-A_{nM})+a_n+a_m \tag{30}$$

3. Using generator powers from the base case, determine

$$B_{MM} = \frac{(P_L)_{\text{base case}} - \sum_{n=1}^{N}\sum_{m=1}^{N} P_n\mathbf{B}_{nm}P_m}{\left(\sum_{m=1}^{N} P_m\right)^2} \tag{31}$$

4. For each value of n and m with $n \geqq m$, calculate

$$B_{nm} = B_{mn} = \mathbf{B}_{nm} + B_{MM} \tag{32}$$

The B_{nm} coefficients calculated by this procedure will be called new total loss coefficients. Because of the additional assumption required in the derivation, the total loss coefficients will not predict incremental losses as well as the incremental loss coefficients themselves.

Examples

EXAMPLE I

The first illustration of the preceding theory is made on a simple system which has already been presented in reference 4. The impedance diagram and the base case load flows are shown in Fig. 2, and additional generation data for several other dispatches are listed in Table I, as obtained from reference 4. The system loss for each case, found by summing the I^2R loss in each line, is also listed in Table I. The base case data used for calculating the loss formula are given in Table II. The generator Q/P ratios are taken as the slopes of the linear approximations to their P-Q characteristics, as plotted from the data in Table I.

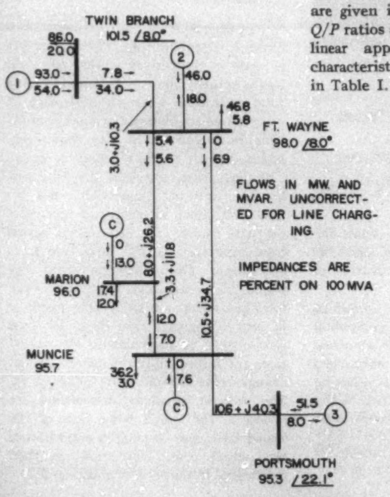

Fig. 2 (left). Impedance diagram and base case load flows

First, A_{nm} coefficients will be calculated. Generator 1 is chosen as the swing machine. The self- and mutual impedance of the generators with generator 1 grounded are calculated to be

$Z_{11}=Z_{12}=Z_{13}=0+j0$

$Z_{22}=Z_{23}=0.0300+j0.1030;\ K_{22}=K_{23}=0.291$

$Z_{33}=0.1905+j0.688;\ K_{33}=0.277$

The D_{nm} quantities of equation 19 are calculated in tabular form in Table III. From the base case data equation 20 gives

$$(dP_L/dP_{2-1})_{\text{base case}} = 2(0.291)\tan 0.0° = 0.0000$$

$$(dP_L/dP_{3-1})_{\text{base case}} = 2(0.277)\tan 14.1° = 0.1391$$

The calculation of the w_n in equation 21 is shown in Table IV. The incremental loss coefficients A_{nm} are found from equation 22 to be

$$A_{nm} = \begin{array}{cccc} & m=1 & 2 & 3 \\ n=1 & 0.0000 & 0.0000 & 0.0000 \\ 2 & -0.0345 & 0.0357 & 0.0305 \\ 3 & -0.0605 & 0.0103 & 0.3695 \end{array}$$

These coefficients are in per unit on a 100-megavolt-ampere (mva) base.

The generation data do not include cases where generation is exchanged between the swing machine and only one other. Therefore, the incremental coefficients are used to obtain total loss coefficients. The a_n quantities are cal-

1	0.930	−0.0345	−0.0321	−0.0605	−0.0563
2	0.460	−0.0345	−0.0159	−0.0605	−0.0278
3	0.515	−0.0403	−0.0208	−0.0605	−0.0312
Total	1.905		−0.0688		−0.1153
		a_2	−0.0181	a_3	−0.0303

culated in Table V according to equation 29. Then, equation 30 is used to calculate the $\mathbf{B}_{nm}$ coefficients, e.g.

$$\mathbf{B}_{32}=(1/2)(0.0103+0.0605)-0.0303-0.0181=-0.0130$$

The resulting $\mathbf{B}_{nm}$ coefficients are

$$\mathbf{B}_{dm}=\begin{array}{cccc} & m=1 & 2 & 3 \\ n=1 & 0.0000 & X & X \\ 2 & -0.0181 & -0.0011 & X \\ 3 & -0.0303 & -0.0130 & 0.1544 \end{array}$$

The value of B_{11} is chosen to make the total loss formula fit the base case loss of 0.0370 per unit. Equation 31 gives the result: $B_{11}=0.0129$. Adding B_{11} to all $\mathbf{B}_{nm}$ coefficients gives the final matrix in per unit on 100 mva

$$B_{nm}=\begin{array}{cccc} & 1 & 2 & 3 \\ 1 & 0.0129 & & \\ 2 & -0.0052 & 0.0118 & \\ 3 & -0.0173 & -0.0001 & 0.1673 \end{array}$$

This matrix is symmetrical. These total loss coefficients may be compared with those calculated by Kirchmayer's method.[4]

A comparison between the actual loss, the loss calculated by the foregoing B_{nm} coefficients, and the loss calculated by Kirchmayer's B_{nm} coefficients for each case in Table I is given in Table VI. Fig. 3 presents a graphical comparison. It is felt that for this system the new loss coefficients provide a closer correlation between calculated and actual losses than do the Kirchmayer loss coefficients, although both are quite satisfactory.

EXAMPLE II

A practical application of the previous theory was made to a somewhat simplified representation of the 110-kv transmission system of the Niagara Mohawk Power Corporation. Although the resistance-reactance ratio is fairly uniform throughout the system, the interconnected New York State Electric and Gas Corporation system has been replaced by a reactance equivalent so that the effect on losses in the Niagara Mohawk Power Corporation from interchange power with the New York State Electric and Gas Corporation may be estimated. Fig. 4 is a combined impedance diagram and base case load study.

Oswego was chosen as the swing machine, and the open-circuit self- and mutual impedances of the generators with Oswego grounded were measured on the network analyzer, the results being presented in Table VII. Incremental loss coefficients were then calculated, assuming that all generators had Q/P ratios equal to zero except for Huntley, Dunkirk, and Albany. The slopes of their P-Q characteristics were used for these plants, the respective values being −0.265, −0.255, and −0.170.

* This matrix is symmetrical.

The A_{nm} coefficients are presented in Table VIII. New total loss coefficients were then calculated from the incremental loss coefficients, the results being presented in Table IX.

Several load studies were made to determine the incremental losses when generation was exchanged between Oswego and another generator. The losses were calculated by each of the following methods:

1. Brownlee formula, equation 8.
2. Incremental loss formula (A_{nm} coefficients).
3. New total loss formula (B_{nm} coefficients).
4. Kirchmayer total loss formula.

In addition, the incremental transmitted power was calculated by equation 7. The results are presented in Figs. 5 through 12 along with the actual losses found by summing the I^2R loss in each line and the actual incremental transmitted powers.

An arbitrarily selected criterion for judging the accuracy of the various formulas was that incremental rates should be accurate to at least 1/10th mil per kilowatt-hour at the 4-mil level. According to equation 26, this means that the allowable discrepancy between actual and calculated incremental losses should not exceed 2.5 megawatts (mw) for a 100-mw swing of generation. This criterion is satisfied for all swings except for Dunkirk and Binghamton. For the Dunkirk swing and the new total loss formula is outside the acceptable range, but the Brownlee and the incremental formula are just inside. Apparently the interaction between Dunkirk and Huntley is causing the Brownlee formula to give somewhat erroneous results. For the Binghamton swing the Brownlee and the incremental formula are just on the borderline. The new total loss formula is outside the acceptable range. The failure of the Brownlee formula in this case is ascribed to the unrealistic assumption of pure reactance tie lines. Also of interest is the fact that the voltage in the neighborhood of Deerfield had to be raised with increasing Deerfield generation to prevent the generators there from operating at a leading power factor. The accuracy of the Brownlee formulas is still good in this case, but a definite error in the incremental transmission formula is observed.

A final test of the formulas was made by scaling all loads to 70 per cent of their value in Fig. 4. Two load studies were made in which some of the Oswego generation was swung to Huntley. The

results are shown in Table X. It is seen that the Brownlee formulas and the incremental formulas are in good agreement with the actual values. The Kirchmayer formula gives a somewhat closer agreement with the actual total loss than does the new total loss formula, although both are satisfactory.

In all test cases, then, the Brownlee formulas and the incremental loss formula displayed acceptable accuracy for economic scheduling purposes. As must be expected from the approximations in its derivation, the new total loss formula is less accurate than the incremental loss formula. The Kirchmayer total loss formula provided an excellent correlation with the actual losses.

Conclusions

On the basis of the preceding theory and numerical cases, it is concluded that the Brownlee theory and the new loss formulas are applicable to practical electric utility systems at least in those cases where all important transmission is at the same voltage level. The Brownlee formulas appear to be about as accurate in most cases as the Kirchmayer B_{nm} coefficients. It has also been demonstrated that incremental and total loss coefficients can be obtained with considerably less computation than has hitherto been possible, and that these coefficients display satisfactory accuracy except where a wide variation in reactance-resistance ratios is encountered. It is hoped that others interested in the problems of economic scheduling will apply the theory developed in this paper and so determine for themselves its advantages and disadvantages.

Appendix I. Derivation of Incremental Loss Coefficients

The derivation of incremental loss coefficients, already outlined in equations 19 through 22, is now presented. The correctness of the Brownlee formulas, equations 3, 4, and 5, is assumed. Additional assumptions are listed where needed.

Continuing the use of the system in Fig. 1, the law of cosines and equation 9 give

$$|E_1-E_2|^2=V_1^2+V_2^2-2V_1V_2\cos(\theta_1-\theta_2)$$
$$=(Z_{11}I_1+Z_{12}I_2)(Z_{11}^*I_1^*+Z_{12}^*I_2^*) \quad (33)$$

Differentiating with respect to θ_1 and noting that only I_1 is variable

$$2V_1V_2\sin(\theta_1-\theta_2)=Z_{11}\frac{dI_1}{d\theta_1}(Z_{11}^*I_1^*+$$
$$Z_{12}^*I_2^*)+Z_{11}^*\frac{dI_1^*}{d\theta_1}(Z_{11}I_1+Z_{12}I_2) \quad (34)$$

Ignoring the correction term in equation 16 gives

$$\frac{dP_L}{d\theta_1}=\frac{2V_1V_2}{Z_{11}Z_{11}^*}R_{11}\sin(\theta_1-\theta_2)$$
$$=2R_{11}Re\left[\frac{dI_1^*}{d\theta_1}\left(I_1+\frac{Z_{12}}{Z_{11}}I_2\right)\right] \quad (35)$$

According to equation 11

$$\frac{dI_1^*}{d\theta_1}=\frac{1}{Z_{11}^*}\frac{dE_1^*}{d\theta_1}=\frac{-jE_1^*}{Z_{11}^*} \quad (36)$$

Then, letting α_{nm} be the angle of Z_{nm}, equation 35 becomes

$$\frac{dP_L}{d\theta_1}=2R_{11}Re\left[\frac{-j}{Z_{11}^*}\left(E_1^*I_1+\frac{Z_{12}}{Z_{11}}E_1^*I_2\right)\right]$$
$$=\frac{2R_{11}}{|Z_{11}|}Re\left(V_1|I_1|\underline{/\phi_1-\theta_1+\alpha_{11}-90^\circ}+\right.$$
$$\left.\left|\frac{Z_{12}}{Z_{11}}\right|\frac{V_1}{V_2}V_2|I_2|\underline{/\phi_2-\theta_2+\theta_2-\theta_1+\alpha_{12}-90^\circ}\right)$$
$$=\frac{2R_{11}}{|Z_{11}|}\left(V_1|I_1|\sin(\phi_1-\theta_1+\alpha_{11})+\right.$$
$$\left.\left|\frac{Z_{12}}{Z_{11}}\right|\frac{V_1}{V_2}V_2|I_2|\sin(\phi_2-\theta_2+\theta_2-\theta_1+\alpha_{12})\right)$$
$$=\frac{2R_{11}}{|Z_{11}|}[V_1|I_1|[\sin(\phi_1-\theta_1)\cos\alpha_{11}+$$
$$\cos(\phi_1-\theta_1)\sin\alpha_{11}]+\left|\frac{Z_{12}}{Z_{11}}\right|\frac{V_1}{V_2}V_2|I_2|\times$$
$$[\sin(\phi_2-\theta_2)\cos(\theta_2-\theta_1)\cos\alpha_{12}-$$
$$\sin(\phi_2-\theta_2)\sin(\theta_2-\theta_1)\sin\alpha_{12}+$$
$$\cos(\phi_2-\theta_2)\sin(\theta_2-\theta_1)\cos\alpha_{12}+$$
$$\cos(\phi_2-\theta_2)\cos(\theta_2-\theta_1)\sin\alpha_{12}]] \quad (37)$$

Noting that $R_{nm}=|Z_{nm}|\cos\alpha_{nm}$, $X_{nm}=|Z_{nm}|\sin\alpha_{nm}$, $P_n=V_n|I_n|\cos(\phi_n-\theta_n)$, and $Q_n=-V_n|I_n|\sin(\phi_n-\theta_n)$, equation 37 finally becomes

$$\frac{dP_L}{d\theta_1}=\frac{2R_{11}}{|Z_{11}|^2}\left[P_1X_{11}-Q_1R_{11}+\frac{V_1}{V_2}P_2\times\right.$$
$$[\cos(\theta_2-\theta_1)X_{12}+\sin(\theta_2-\theta_1)R_{12}]+$$
$$\left.\frac{V_1}{V_2}Q_2[\sin(\theta_2-\theta_1)X_{12}-\cos(\theta_2-\theta_1)R_{12}]\right] \quad (38)$$

Now, ignoring the correction terms in equation 17

$$\frac{dP_{1-2}}{d\theta_1}=\frac{V_1V_2}{|Z_{11}|^2}X_{11}\cos(\theta_1-\theta_2) \quad (39)$$

so that dividing equation 38 by equation 39 gives

Table X. Results for 70-Per-Cent Load Level in Mw

Incremental Losses			Incremental Transmitted Power		Total Losses			
Brownlee	Incremental	Actual	Brownlee	Actual	Case	New Total	Kirchmayer Total	Actual
−2.41	−2.90	−2.6	78.1	82	1	27.2	26.0	26.7
					2	23.9	25.2	24.1

$$\frac{dP_L}{dP_{1-2}} = \frac{2R_{11}}{V_2 \cos(\theta_1-\theta_2)}\left\{\frac{P_1}{V_1}\left(1-\frac{Q_1}{P_1}\frac{R_{11}}{X_{11}}\right)+ \frac{X_{13}P_3}{X_{11}V_3}\left[\cos(\theta_3-\theta_1)\left(1-\frac{Q_3}{P_3}\frac{R_{13}}{X_{13}}\right)+ \sin(\theta_3-\theta_1)\left(\frac{R_{13}}{X_{13}}+\frac{Q_3}{P_3}\right)\right]\right\} \quad (40)$$

Equation 40 is exact in so far as the elimination of the correction terms in equations 16 and 17 is justified. It is not useful unless reasonable assumptions about the constancy of the various terms can be made. As the simplest assumption, the usual practice of taking the terms as constants equal to their values in the base case is introduced. Writing equation 40 for the general case with several other generators or loads besides the first two

$$\frac{dP_L}{dP_{1-2}} = \sum_m D_m P_m \quad (41)$$

where

$$D_m = 2K_{11}X_{1m} \times \left(\frac{\cos(\theta_m-\theta_1)(1-s_mK_{1m})+ \sin(\theta_m-\theta_1)(K_{1m}+s_m)}{V_mV_2\cos(\theta_1-\theta_2)}\right) \quad (42)$$

with

$s_m = Q_m/P_m$ and $K_{nm} = R_{nm}/X_{nm}$

Equation 41 is not useful as it stands because the summation is over all loads as well as all generators, the coefficient of generator 2 being zero. The loads may be eliminated and the power output of generator 2 introduced if the usual assumption of proportional, constant power-factor loads is made. Then, the summation over all loads may be replaced by a single term K_RP_R whose magnitude is proportional to the total load P_R. The constant of proportionality, K_R is not known, since no D_m coefficients have been calculated for the loads. However, it may be evaluated indirectly from the base case. First make the substitution

$$P_R = -\sum_{m=1}^{N} P_m \quad (43)$$

where N generators are assumed. Equation 43 assumes that the total generation equals the total load with the system losses being negligible. Then, equation 41 becomes

$$\frac{dP_L}{dP_{1-2}} = \sum_{m=1}^{N}(D_m-K_R)P_m \quad (44)$$

K_R is chosen so that dP_L/dP_{1-2} has the correct base case value, as determined from equation 5, which is rewritten as

$$\frac{dP_L}{dP_{1-2}} = 2K_{11}\tan(\theta_1-\theta_2) \quad (45)$$

Equation 44 may be rewritten as

$$\frac{dP_L}{dP_{1-2}} = \sum_{m=1}^{N} A_mP_m \quad (46)$$

with the summation extending only over the generators. A similar equation can be derived for each pair of generators, but only the N-1 equations between one generator and all others are necessary. Letting M be the chosen plant, the incremental loss formula may be written as

$$\frac{dP_L}{dP_{n-M}} = \sum_{m=1}^{N} A_{nm}P_m \quad (47)$$

All coefficients with $n=M$ are taken as 0.

Appendix II. Derivation of New Total Loss Coefficients

The derivation of the new total loss coefficients from the incremental loss coefficients is now presented. The theory behind the derivation is that the incremental loss formula may be used to calculate the total loss for some dispatch of generation by determining the incremental loss obtained every time a plant is changed from its base case value to its value in the dispatch for which the total loss is desired. Because the incremental loss formula concerns changes of generation at constant system loads, the total loss for a dispatch at a system load different from that of the base case cannot directly be calculated by the foregoing procedure. Therefore, an additional assumption is introduced, which is that, if all generations in the base case are multiplied by the factor k with a corresponding change in each load, the total loss is multiplied by k^2, corresponding to the assumption of fixed bus voltages, making currents and powers approximately proportional. Following this assumption, the base case generation is scaled by the ratio of total generation in the dispatch whose loss is desired to the total generation in the base case. The incremental loss formulas are then applied to go from the scaled base case to the given dispatch. Since the incremental loss formulas were derived assuming a fixed system load, a slight additional error is introduced by neglecting the effect of incremental losses on the output of the swing machine when the various increments are found.

The derivation is illustrated for a 4-plant system; the extension to a larger number will be evident. The incremental loss formula, with plant 4 being the swing machine, is

$$\frac{dP_L}{dP_{1-4}} = \sum_{m=1}^{4} A_{1m}P_m$$

$$\frac{dP_L}{dP_{2-4}} = \sum_{m=1}^{4} A_{2m}P_m$$

$$\frac{dP_L}{dP_{3-4}} = \sum_{m=1}^{4} A_{3m}P_m \quad (48)$$

Base case powers and power loss will be indicated by the subscript *o*. Define the ratio k by

$$k = \sum_{m=1}^{4} P_m \Big/ \sum_{m=1}^{4} P_{mo} \quad (49)$$

and define the difference in power outputs between the case for which the total loss is desired and the scaled base case as p_m

$$p_m = P_m - kP_{mo} \quad (50)$$

Then, the desired power loss is found by applying the incremental loss formulas for finite increments. First, plant 1 is changed from its scaled base case value to its final value, the incremental loss being calculated. The decrease in P_4 is assumed equal to the increase in P_1. This is repeated for plants 2 and 3. Thus

$$\begin{aligned} P_L = {} & k^2P_{Lo} + \left[A_{11}\left(kP_{1o}+\frac{p_1}{2}\right)+A_{12}kP_{2o}+ A_{13}kP_{3o}+A_{14}\left(kP_{4o}-\frac{p_1}{2}\right)\right]p_1 + \\ & \left[A_{21}(kP_{1o}+p_1)+A_{22}\left(kP_{2o}+\frac{p_2}{2}\right)+ A_{23}kP_{3o}+A_{24}\left(kP_{4o}-p_1-\frac{p_2}{2}\right)\right]p_2 + \\ & \left[A_{31}(kP_{1o}+p_1)+A_{32}(kP_{2o}+p_2)+ A_{33}\left(kP_{3o}+\frac{p_3}{2}\right)+A_{34}\left(kP_{4o}-p_1-p_2-\frac{p_3}{2}\right)\right]p_3 = \\ & k^2P_{Lo}+kp_1\sum_{m=1}^{4}A_{1m}P_{mo}+ kp_2\sum_{m=1}^{4}A_{2m}P_{mo}+kp_3\sum_{m=1}^{4}A_{3m}P_{mo}+ \\ & (1/2)(A_{11}-A_{14})p_1^2+(1/2)(A_{22}- A_{24})p_2^2+(1/2)(A_{33}-A_{34})p_3^2+ \\ & (A_{21}-A_{24})p_2p_1+(A_{31}-A_{34})p_3p_1+ (A_{32}-A_{34})p_3p_2 \end{aligned} \quad (51)$$

If in equation 51, equation 50 is substituted for p_m and equation 49 for k and the expression simplified

$$\begin{aligned} P_L = {} & C\left(\sum_{m=1}^{4}P_m\right)^2+P_1\left(\sum_{m=1}^{4}A_{1m}P_{mo}- (A_{11}-A_{14})P_{1o}-(A_{21}-A_{24})P_{2o}- (A_{31}-A_{34})P_{3o}\right)\sum_{m=1}^{4}P_m\Big/\sum_{m=1}^{4}P_{mo}+ \\ & P_2\left(\sum_{m=1}^{4}A_{2m}P_{mo}-(A_{21}-A_{24})P_{1o}- (A_{22}-A_{24})P_{2o}-(A_{32}-A_{34})P_{3o}\right)\times \sum_{m=1}^{4}P_m\Big/\sum_{m=1}^{4}P_{mo}+ \\ & P_3\left(\sum_{m=1}^{4}A_{3m}P_{mo}- (A_{31}-A_{34})P_{1o}-(A_{32}-A_{34})P_{2o}- (A_{33}-A_{34})P_{3o}\right)\times\sum_{m=1}^{4}P_m\Big/\sum_{m=1}^{4}P_{mo}+ \\ & (1/2)(A_{11}-A_{14})P_1^2+(1/2)(A_{22}- A_{24})P_2^2+(1/2)(A_{33}-A_{34})P_3^2+ (A_{21}-A_{24})P_2P_1+(A_{31}-A_{34})\times P_3P_1+(A_{32}-A_{34})P_3P_2 \end{aligned} \quad (52)$$

where C is a constant involving the base case power outputs and power loss. It will be determined indirectly. Now define the quantities

$$a_n = \frac{\sum_{m=1}^{n}A_{n4}P_{mo}+\sum_{m=n+1}^{4}(A_{nm}-A_{mn}+A_{m4})P_{mo}}{2\sum_{m=1}^{4}P_{mo}} \quad (53)$$

The numerator in equation 53 is the same as the quantities in parentheses in equation 52. Then, equation 52 may be written as

$$P_L=\sum_{n=1}^{4}\sum_{m=1}^{4}P_nB_{nm}P_m \qquad (54)$$

where for $n \geq m$

$$B_{nm}=B_{mn}=C+a_n+a_m+(1/2)(A_{nm}-A_{n4}) \qquad (55)$$

It is seen that C is identical with B_{44}. B_{44} is found by making equation 54 fit the base case loss. Thus, choose B_{44} so that

$$P_{Lo}=\sum_{n=1}^{4}\sum_{m=1}^{4}P_{no}(B_{nm}-B_{44})P_{mo}+ B_{44}\sum_{n=1}^{4}\sum_{m=1}^{4}P_{no}P_{mo} \qquad (56)$$

Generalized to the case of N plants, the foregoing derivation is outlined in equations 29 through 32.

Discussion

W. R. Brownlee (Southern Services Inc., Birmingham, Ala.): In his justification of the phase-angle method, the author has derived certain correction terms appearing in equations 16 and 17. It appears that these are based on constant current from the third generator. In an actual power system, the current from this generator would vary, especially in its phase position, since the phase angle of the bus voltage at generator no. 3 would move forward as required to keep its power output constant when generation is being increased at plant 1 and reduced at plant 2. This influence may be quite difficult to introduce in equations, but I am confident that full recognition of this fundamental fact of power system performance would reduce the magnitude of the correction terms to a negligible value.

In his conclusion, the author avoids a positive assertion that phase-angle equations and the new loss constants based thereon are applicable to systems with superposed high-voltage transmission. It is believed that this lack of complete confidence may arise from Fig. 11 where power is exchanged between Oswego and a foreign system. The foreign ties have been represented, as shown in Fig. 4, by pure reactance. My previous paper (ref. 1 of the paper) had only a brief mention of the use of a pure reactance line for a foreign path. This concept has been found quite useful to determine the incremental losses between two plants on a particular system when some 25 per cent of the interchange between these plants may pass through a foreign system. However, when this expedient is utilized, as the author has done in Fig. 4, the system then becomes of the line type with a high-reactance path between plant 9 and the intermediate generation and the usual reactance-resistance ratio from this equivalent intermediate plant to plant no. 4. This system should be so treated by assigning all of resistance indicated between plants 4 and 9 to a section between plant 4 and the equivalent intermediate plant, assigning a reactance to this section based on the ratio shown between plants 3 and 4, and assigning the remaining reactance from the intermediate plant to plant 9. Such a calculation results in an indicated loss between the base case and a flow of 49.5 mw to Binghamton of 6.45 mw, or a total loss of some 36.6 mw, which is only slightly above the actual loss curve of Fig. 11. This illustrates the flexibility of the direct phase-angle method for dealing with high-reactance paths.

The formulas in this paper make use of incremental loss referred to the average of sending end and receiving end power, whereas previous analyses have referred this loss to the designated terminal. With the proper designations followed, the author's equation 26 is equivalent to equation 11 of my earlier paper (ref. 1 of the paper). However, the approximations shown as equation 27 may not be justifiable for substantial angles. For example, with an incremental loss from one plant to another of 30 per cent, the economic fuel ratio by equation 26 would be 1.429, whereas, by equation 27, it could be either 1.353 or 1.548. To avoid confusion, it is suggested that a bar be used over the letters representing average sending and receiving power or incremental losses referred to such power as $\overline{dP}_{12}$ or $\overline{M}_{12}$.

An interesting comparison of the use of constants calculated has been provided by the new method and those advocated by Glimn, Habermann, Kirchmayer, and Stagg (ref. 4 of the paper). The author states that the total losses are derived more accurately by the new method (based on phase angles) when compared with earlier methods which made no use of phase-angle incrementals. The information in Fig. 3 provides incom-

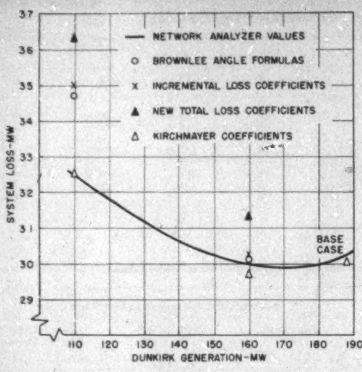

Fig. 13. Comparison of actual and calculated losses for exchange of generation between Dunkirk and Oswego

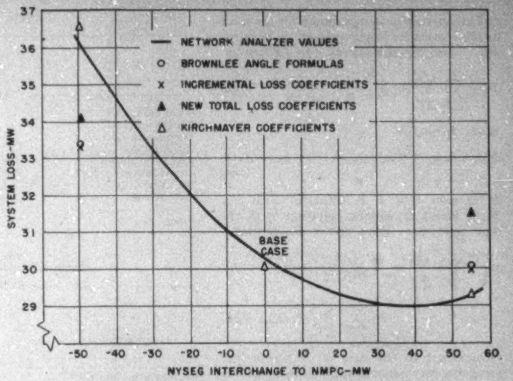

Fig. 14. Comparison of actual and calculated losses for exchange of generation between New York State Electric and Gas and Oswego

plete support of this assertion. Two of the points shown are definitely better by the new method, but the point on the left-hand side of the figure appears to show better correlation for the earlier constants. However, this point is in serious error in the paper, as is shown in Table XI. The discrepancy indicated for case 1 amounts to over 4 percent of the total system load and is greater than the total I^2R losses. Accordingly, it would not be expected that a straightforward formula would provide an adequate indication of the measured losses, and the fact that the earlier formula (ref. 4 of the paper) appeared to do so is not complimentary to that method. With this incorrect case deleted, the new formulas show better correlation than the earlier formula.

Another check on the new total loss constants may be made by comparing the incremental losses between pairs of plants of the Portsmouth-Fort Wayne-Twin Branch system. The actual incremental loss from Portsmouth to Fort Wayne was calculated by superposing a flow of 0.1 mw at Portsmouth toward Fort Wayne, with the proper change in kilovar flow, and calculating the loss in each line section before and after. A similar analysis gives the change in loss for a flow of 0.1 mw to Portsmouth from Fort Wayne, the average value being a genuine incremental. Table XII provides details of these calculations. Table XIII shows the calculation of the incremental losses by phase angles and by the new total loss constants. The new constants yield a satisfactory result, but the value calculated directly by phase angles is closer to the actual incremental loss.

The new method presented has several important advantanges over those published previously. The derivation of the constants is much simpler, and some of the more fantastic assumptions are avoided. There is still a suspicion of w' although the treacherous Q/P ratio has been properly relegated to the background. Finally, the new method is evidence of the growing conviction that adequate co-ordination of fuel and transmission requires loss constants with accuracy focused on incremental losses, rather than total losses.

A. F. Glimn and L. K. Kirchmayer (General Electric Company, Schenectady, N. Y.): Mr. Cahn is to be commended for his thorough analysis of and his contributions to methods of calculating transmission losses. In general, good loss formula results have been obtained by all the methods treated. It is particularly gratifying that the results of the so-called Kirchmayer formula give the best correlation between actual and calculated losses in the study of the Niagara Mohawk system.

The results obtained by the simplified Cahn formulas and the Brownlee formula appear to be in error principally in the swings between Oswego and Dunkirk and Oswego and New York State Electric and Gas. In the Dunkirk swing of approximately 80 mw, Fig. 13, the error in the change in loss by the Kirchmayer formula was negligible. The error was 2.2 mw by the Brownlee formula, 2.5 mw for the Cahn incremental loss formula, and 3.8 mw for the Cahn total loss formula. In Fig. 14, for the swing between Oswego and New York State Electric and Gas, it is seen that the error in the change in loss for the 100-mw swing was 3.5 mw for the Brownlee formula, 3.5 mw for the Cahn incremental loss formula, 4.2 for the Cahn total loss formula, and 0.5 mw for the Kirchmayer formula.

These errors result chiefly from the fact that neither the Brownlee formula nor the simplified Cahn formulas correctly consider the effects of intermediate load and generation when the circuits have different reactance-resistance ratios. Inspection of

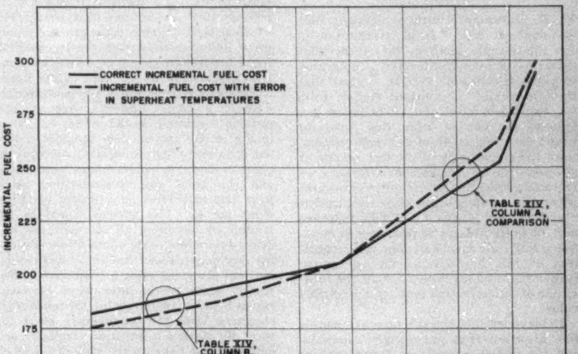

Fig. 15. Incremental fuel cost curves for station P7

Table VII shows that variation in reactance-resistance ratio need not be excessive to produce such errors.

The nature of these discrepancies has been previously pointed out in our discussion last year of Mr. Brownlee's paper (see ref. 1 of the paper). Mr. Cahn has contributed to a proper understanding of the Brownlee approach through means of equations 16 and 17, which also indicate the nature of the errors introduced by the Brownlee method. These equations, although derived for slightly different assumptions than used by Glimn and Kirchmayer, can be employed to calculate the error curves involved in the application of the Brownlee formula as presented in our discussion of the Brownlee paper. The Kirchmayer formula does not rely on any assumptions with regard to the reactance-resistance ratios of the lines in the system. The errors illustrated by Mr. Cahn's study are usually significant in systems in which the transmission lines are at different voltage levels and in which transformers appear.

Has the author had an opportunity to use his more exact approach in his study of the Niagara Mohawk system?

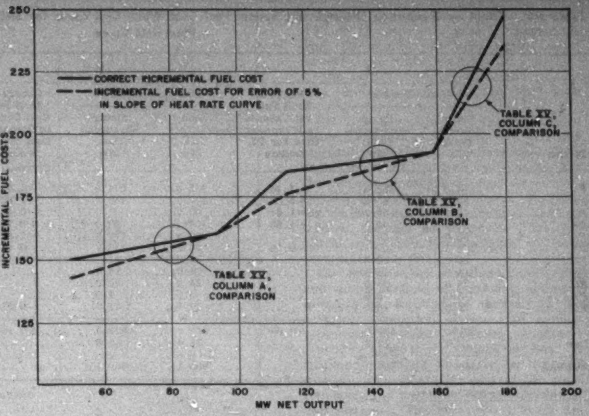

Fig. 16. Incremental fuel cost curves for station P2

R. H. Travers (Ohio Edison Company, Akron, Ohio) and **R. W. Long** (Westinghouse Electric Corporation, E. Pittsburgh, Pa.): Mr. Cahn has done an admirable job of extending Mr. Brownlee's work in the development of loss formulas to the form in which this theory can be used in system operation and in economic dispatching. The methods of approach used by both Mr. Brownlee and Mr. Cahn are unique and depend to some extend on intuition. Therefore, for a complex system, it is not feasible to present a rigorous mathematical derivation for the constants developed.

Approximations of derivation are introduced when some of the mathematical terms of an expression are dropped with the reasoning that their numerical significance is negligible. This is a device frequently utilized in many branches of applied engineering and, when it is used, it necessitates setting up some criteria of accuracy for the final results.

In this paper the "criterion for judging the accuracy of the various formulas was that incremental rates should be accurate to at least $^1/_{10}$th mil per kilowatt-hour at the 4-mil level." In terms of the resulting power dispatched to a particular station this statement is somewhat ambiguous. If the slope of the increment curve is steep, a shift of $^1/_{10}$th mil in incremental cost might mean a shift of 1 or 2 mw in power output. However, at lower loadings on that same station, a similar shift in incremental cost could change output by as much as 30 or 40 mw.

This suggests that possibly the point in the development of economic dispatching has been reached where the loss formulas are relatively more accurate than the basic fuel cost data. In the newer plants equipped with modern instrumentation in the steam end, it is possible to get well-defined input-output data from which incremental heat rate curves of good accuracy can be determined. This is not necessarily true of the older plants.

In the co-ordination equations for economic dispatch recognizing incremental transmission loss, the predominant factor is the station incremental fuel cost. To illustrate this, we have made a set of 11 economic dispatch solutions using erroneous data of various types, and calculated the resulting change in total fuel input cost to the system caused by these errors.

Fig. 15 shows the correct incremental cost curve for one station as a solid curve. The dash curve is another increment cost curve determined from data which involved errors in reading superheat temperatures. Two system comparisons are made with these data. For a 1,052-mw system generation, this station should carry 203 mw. The erroneous curve, about 4 per cent in error at the 200-mw region, yields a dispatch which allocated only 197 mw to this station, a shift of 6 mw. These 6 mw were picked up over several other stations on the system, as shown in Table XIV, column *A*. All of these incremental shifts in generation were then evaluated at bus-bar costs, and the increased fuel costs at the other stations in picking up this 6 mw was $1.20 more than the saving in fuel cost resulting from unloading station *P7* by 6 mw. This value of $1.20 may seem small but, as an error of this magnitude persists, it integrates with time and can easly reach several thousand dollars a year.

Another solution at the 596-mw system generation level where this station is loaded at 82-mw showed a shift of 12 mw, this time an increase in *P7* load caused by apparent lower bus-bar cost of about 4 per cent. Here again, evaluation of the shifts at all plans showed a net increased cost to the system of $1.31, as shown in Table XIV, column *B*. In this example no correction has been made for the increased generation which would be necessary to carry the same customer load since losses have increased.

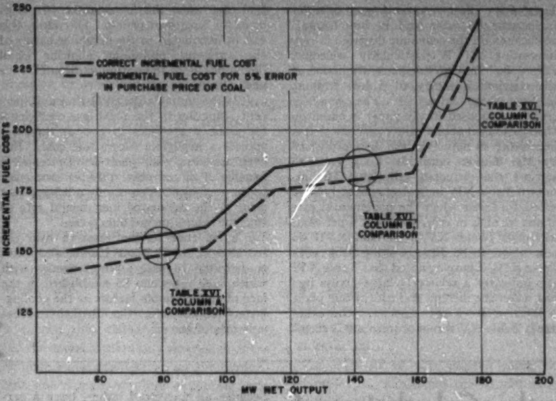

Fig. 17. Incremental fuel cost curves for station P2

This correction would tend to increase the magnitude of the error.

Fig. 16 shows similar incremental cost curves for another station. In this case, the error is caused by a 5-per-cent error in slope of the incremental heat rate curve. This type of error can easily occur, since these heat rate curves are plotted from test data and are usually someone's judgement as to the best curve which fits a cloud of test points. Here the solutions are at system net load levels of approximately 600 mw, 900 mw, and 1,150 mw. Using the erroneous incremental cost curve, increased loadings are obtained for *P2* of 3.3 mw, 4.1 mw, and 2.2 mw respectively. Evaluating these shifts for total changes in system fuel cost results in increases of $.09, $.16, and $.23, as shown in Table XV, columns *A*, *B*, and *C*. At the points where these solutions were obtained, the bus-bar costs for station *P2* were in error by approximately 2 per cent or less.

Fig. 17 again relates to station *P2* and shows an error curve for a 5-per-cent reduction in fuel cost. At the same system net load levels as before, the dispatches using this erroneous curve increase loading of the station by 13.5 mw, 17.1 mw, and 3.6 mw respectively. Because of this error in fuel cost at station *P2*, the fuel cost input to the system was increased by $.65, $.85, and $.26, as shown in Table XVI, columns *A*, *B*, and *C*.

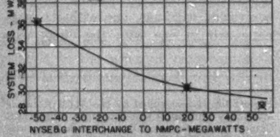

Fig. 18. Comparison of actual and calculated losses for exchange of generation between New York State Electric and Gas and Oswego

— Actual
⊙ Modified Brownlee
× Revised incremental

Station *P2* has the highest over-all incremental transmission loss penalty of any station on this system. Therefore, all the *B* constants relative to this station were arbitrarily reduced by 10 per cent and new dispatches were obtained for the same three levels of system net load as before. The resulting increases in loading of *P2* were 6.0 mw, 10.0 mw, and 2.5 mw and the changes in fuel cost to the system were $.21, $.70 and $.03, as shown in Table XVII, columns *A*, *B*, and *C*.

From these data it is apparent that a change of 10 per cent in a group of *B* constants is less serious economically than a 4 to 5-per-cent change in a plant incremental fuel cost, and in one comparison less serious than a 2-per-cent change in fuel cost. Based on these data, it appears desirable for the steam production people to examine their methods more closely so as to give better basic cost data for use in economic dispatching.

By the same token, however, efforts should be made to obtain better loss formulas because there are many instances where these formulas are being used to determine incremental losses for sale power, and these incremental losses are then used in billing calculations. For this latter purpose it is still necessary to strive for the highest accuracy possible in these *B* constants.

C. R. Cahn: I am grateful for the interesting and informative discussions. Mr. Brownlee has rightly indicated that the correction terms in equations 16 and 17 assume constant current at all generators other than the two between which generation is exchanged. An attempt to hold constant powers at the other generators leads to great analytical complication, and it becomes difficult to draw any general conclusions from the results. In some simple cases, however, the correction terms in equations 16 and 17 have been shown to give reasonably accurate corrections to the basic Brownlee formulas.

Mr. Brownlee points out that a study of Table I shows a system load nearly 9 mw more for case 1 than for the base case. Reference to the original load study shows that the increase at each load was not proportional to the base case load power. Correcting the load distribution results in only an 0.2-mw increase in losses so that the Kirchmayer-Glimn formula is still the more accurate one for this case.

Mr. Brownlee has contributed a powerful and simple method of extending his basic formulas to obtain more accuracy in the frequently recurring situation of a line-type system with different reactance-resistance ratios in the various sections. A single intermediate bus may be assumed with an appropriate division of the total resistance and reactance being made to the two sections. The incremental losses are then computed separately for each of the sections.

Illustration of the foregoing is given for the Binghamton and the Dunkirk generation swings for which the basic Brownlee formulas gave somewhat unsatisfactory results, as shown in Figs. 7 and 11. For the Binghamton swing, the total impedance is divided into $j0.1670$ between Binghamton and the equivalent intermediate bus and $0.0422 + j0.1380$ between the intermediate bus and Oswego. The latter section has a reactance-resistance ratio characteristic of the main transmission system. The comparison between actual losses and those calculated by the Brownlee formulas applied to each of the two sections is shown in Fig. 18. In addition, a new incremental loss formula was obtained using the 2-section equivalent. Losses determined with the incremental loss formula are also shown in Fig. 18.

For the Dunkirk swing the total impedance is divided into 0.0130 between Dunkirk and the equivalent intermediate bus and $0.1290 + j0.421$ between the intermediate bus and Oswego. The latter section has a reactance-resistance ratio characteristic of the main transmission system. The losses in the zero-reactance section are calculated by I^2R, assuming that the full output of Dunkirk flows in the

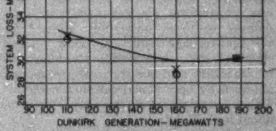

Fig. 19. Comparison of actual and calculated losses for exchange of generation between Dunkirk and Oswego

— Actual
⊙ Modified Brownlee
× Revised incremental

resistance. The incremental loss in the other section is calculated with the Brownlee formulas. The losses calculated in the foregoing manner are shown in Fig. 19 along with the actual losses and those determined by a revised incremental loss formula.

It is seen that an excellent correlation between calculated and actual losses is now obtained for both generation swings, removing any objection to the application of the Brownlee formulas and the new formulas to the system shown in Fig. 4. It is believed that use of the foregoing improvement will also enable a reliable application of the methods of the paper to systems with transmission lines at different voltage levels interconnected by transformer banks. As pointed out by Mr. Glimn and Mr. Kirchmayer, this type of system usually will have a wide variation in the reactance-resistance ratios.

The analysis by Mr. Travers and Mr. Long of the effect of various types of errors in incremental rates and in loss formula coefficients on the economic dispatch is very interesting. It is particularly welcome, since I feel that no adequate discussion of the required accuracy of a loss formula has yet been advanced. The accuracy criterion proposed in the paper is based on observations of actual utility practice. It is interesting to note that the data presented by Mr. Travers and Mr. Long seem to support the proposed criterion. The results of Table XIV indicate a relatively large excess fuel cost when the incremental rate of one plant is in error by about 4 per cent. Although Tables XV, XVI, and XVII do not appear to be directly comparable with Table XIV, it may be noted that Table XVI also indicates a relatively large excess fuel cost when the incremental rate of one plant is in error by 5 per cent. On the other hand, Table XV shows a quite small excess fuel cost when the incremental rate is in error by 2 per cent or less. Of course, this can be attributed to the parabolic nature of the economic minimum, allowing small deviations from the optimum dispatch with negligible error.

It is shown in Table XVII that a 10-per-cent reduction in the total loss coefficients for plant 2 produces in two of three instances a negligible excess fuel cost. But even assuming that plant 2 operates at a penalty of 25 per cent, a 10-per-cent error in the coefficients means only a 2.5-per-cent error in the calculated incremental rate so that the results are not unexpected.

I agree that further research into the representation of plant incremental rates is desirable to assure the accuracy with which such rates can be established in the face of such variable factors as the cooling-water temperature, the British thermal unit rate of the coal, etc.

A New Approach to the Calculation of Synchronous Machine Reactances—Part I

M. E. TALAAT
ASSOCIATE MEMBER AIEE

Synopsis: In Part I of this paper, the 2-reaction theory of synchronous machines[1] is used to derive the torque equation at any slip *s* of the unexcited synchronous motor with one equivalent damper-winding circuit in each axis. It is then shown that this synchronous motor torque equation reduces in the special case of uniform air gap and continuous damper to the torque equation of the induction motor as developed from its equivalent circuit.[2] A paramount criterion for the correctness of any resistance or reactance equations derived for synchronous machines is their reducibility in the special case of uniform air gap and continuous damper to those commonly known for the squirrel-cage induction motor.[2,3]

Equations in terms of dimensions and physical constants are derived in this paper from basic theory of coupled circuits. Also it is shown that all of these equations reduce in the previously mentioned special case of uniform air gap and continuous damper to those universally given[2,3] for the squirrel-cage induction motor. These equations are then inserted in the definitions of transient and subtransient reactances obtained by operational calculus methods.[4] The nomenclature of this paper will be found in Appendix I.

In a later paper, comparison will be made of calculated transient and subtransient reactances based on the equations given here with those given by test and reference,[5] and the discrepancies will be discussed. Also, numerical samples of calculations of the different reactances will be given, using information based on the present paper.

THERE have been many papers on steady-state and transient circuit analysis of synchronous machines, but relatively few presenting design equations for the constants which are used in the analytical theory of synchronous machines.

Needless to say, accurate theoretical analysis of synchronous machine steady-state or transient performance can be greatly jeopardized if the constants to be inserted in the analytical equations or equivalent circuits are themselves inaccurate.

It has been noticed by many designers over a period of time that the unsaturated calculated values of transient and subtransient reactances of synchronous machines, using equations presented in a previous paper[5] on this subject, have yielded results that are often lower than those obtained by test. This has made it necessary for many designers to apply an empirical factor based on experience, to increase their calculated values to approximate more closely the test values of transient and subtransient reactances.

Hence, the need arises in practical design work for a new approach to the subject. The new equations must give unsaturated calculated values which are higher than any test values. This is because all measured values have a certain degree of saturation which tends to give lower values by test than by calculations which neglect saturation.

If saturation factors referred to in the previously mentioned paper[5] were applied, the calculated results will show an even greater discrepancy from test values.

Discussion and Conclusions

In respect to the damper windings, two main points of view are followed in dealing with the calculation of synchronous machine constants. One[6,7] is to consider each two damper bars symmetrically located with respect to the direct axis or quadrature axis as comprising one damper-winding circuit in the direct or quadrature axis respectively. This makes the subsequent subtransient or starting analysis of the machine very involved, and would require the use of the network analyzer which may not be readily available, or may not be economically justified in the majority of cases.

The other point of view,[5,8] which is adopted in this paper, replaces the unsymmetrical damper winding by two equivalent windings, one with its magnetic axis in line with the direct axis

---

Paper 55-6, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted March 18, 1954; made available for printing October 27, 1954.

M. E. TALAAT is with the Elliott Company, Ridgway, Pa.

The author wishes to express his thanks to R. F. Edwards for his criticism, and for his suggestions in regard to the wording of this paper.

(pole center), and the other with its magnetic axis in line with the quadrature axis (interpole center).

This point of view simplifies the analysis of synchronous machines, and is readily applicable to the majority of cases, where a single bar material is used in the damper winding. Where more than one material is used, as in the case of many synchronous motors, one circuit can be added for each additional group of bars of one material, or an equivalent bar material figured[9] for all bars and, hence, one equivalent damper-winding circuit can still be used in each axis.

In this paper, the argument is first advanced that the paramount criterion for the correctness of any resistance or reactance equations derived for the equivalent one damper-winding circuit in each axis is their reducibility in the case of continuous damper and uniform gap, to those universally given for the reflected secondary resistance and secondary reactance of the squirrel-cage induction motor. That this reducibility must be the case is shown in Appendix II, where the induction motor torque equation is obtained by the application of the 2-reaction theory of synchronous machines to the nonexcited case with continuous damper windings and uniform air gap.

In Appendix III the magnetomotive force (mmf) distribution in each of the equivalent damper-winding circuits is studied, and certain coefficients are defined. These are then used in Appendix IV to obtain self-, mutual, and leakage reactances as well as resistance of each equivalent damper-winding circuit referred to the stator side. The results are all shown to reduce for continuous damper and uniform gap to those given for the reflected constants of the squirrel-cage induction motor.[2,3] In Appendix V, equations for the self-mutual, and leakage reactances of the field winding referred to the stator side, are derived. In Appendixes IV and V, it is clearly shown that mutual reactances derived from either side and referred to the stator side are all equal. Their relation to the armature reaction reactances in the direct or quadrature axis is given.

Results from Appendixes IV and V are then inserted in the definition of transient and subtransient reactances obtained from operational calculus methods. This yields equations for reactances which are readily seen to agree qualitatively in form with the equivalent circuits of synchronous machines for transient and subtransient conditions when one equivalent damper winding only is considered in each axis.

No per-unit (pu) system is used in this presentation. This was done in order to present, to beginners in the design field, equations for the reactances of salient-pole synchronous machines on the basis of the principle of coupled circuits and the fundamental concepts of physics with which they have some familiarity.

The equations presented are given in terms of dimensions and physical constants, and they yield values in ohms. If any pu system is to be selected by the design or application engineer, he can simply divide the values obtained by his pu impedance to get the reactances in pu.

In Part II of this paper, numerical examples of calculating the synchronous machine reactances using the equations presented here will be given. The results obtained will be compared with those given by using equations given in reference 5 and those obtained from tests on several machines. A discussion of the discrepancies will be given.

General Theory

In this paper the analysis equations developed are based on the generalized 2-reaction theory of synchronous machines, in which the following assumptions are made.[10]

ASSUMPTIONS

1. Saturation, hysteresis, and eddy currents in all magnetic circuits are neglected. This linearizes the machines. Eddy currents in electric circuits and charging currents between electric circuits or parts of circuits are also ignored.
2. The armature phase winding is distributed in such a way as to produce sinusoidal space distribution of mmf.
3. The pole structure is symmetrical about the axis of the pole. A symmetrical polyphase armature winding is assumed.
4. The variation of armature phase self- and mutual inductances contain only zero and second-harmonic sinusoidal space components.
5. The magnitude of the second-harmonic components of armature phase self- and mutual inductances are equal.
6. The variation of the mutual inductances between any armature phase circuit and any rotor circuit with respect to rotor position is purely sinusoidal.
7. The self- and mutual inductances of all rotor circuits are independent of rotor position. This neglects the effect of the slots.
8. Effective armature winding flux linkages are produced only by the fundamental component of air-gap flux density.

ASYNCHRONOUS TORQUE EQUATION

It is shown in Appendix II that by the use of Park's equations[1] the torque equation of the unexcited synchronous machine with uniform air gap and continuous damper winding at any slip s is given by

$$T=\frac{m}{4}Pe_m^2\frac{-s\alpha_d(x_d-x_d'')}{(r\alpha_d-s\omega x_d'')^2+(s\omega r+\alpha_d x_d)^2}\quad\text{watt-seconds}\qquad(1)$$

(Torque has negative sign for motor action.)

It is further shown in Appendix II that when the definitions of α_d, x_d and x_d'' are introduced in equation 1, then equation 2 results

$$T=-\frac{m}{4}P\frac{e^2m}{\omega}\times\frac{\frac{m}{2}R_{Dd}x_{ad}\frac{m}{2}SX_{aDd}}{\left(r\frac{m}{2}SX_{DDd}+\frac{m}{2}R_{Dd}x_d\right)^2+\left(x_{LD}\frac{m}{2}SX_{aDd}+\frac{m}{2}SX_{LDd}x_d-r\frac{m}{2}R_{Dd}\right)^2}\quad\text{watt-seconds}\qquad(2)$$

which is identical with induction motor torque equation as obtained from circuit theory[2] if the identities given by equations 38 to 45, inclusive, are noticed. Equation 2 leaves no doubt that any of the equations developed for the constants

$$\frac{m}{2}R_{Dd},\ \frac{m}{2}X_{LDd},\ \frac{m}{2}X_{aDd},\ \text{and}\ \frac{m}{2}X_{DDd}$$

for the equivalent 1-circuit damper winding in the direct axis as well as

$$\frac{m}{2}R_{Dq},\ \frac{m}{2}X_{LDq},\ \frac{m}{2}X_{aDq},\ \text{and}\ \frac{m}{2}X_{DDq}$$

for the equivalent 1-circuit damper winding in the quadrature axis must reduce for the case of uniform air gap and continuous damper winding to those normally given for the squirrel-cage induction motor.[2,3]

EQUATIONS FOR DAMPER-WINDING CONSTANTS REFERRED TO STATOR SIDE

In Appendix IV the following equations are derived for leakage, mutual, and self-reactances as well as resistance for each of the equivalent single-circuit damper winding. These are given

$$X_{LDd}=\frac{8fL(Nk_w)^2}{10^8P}\frac{2\pi\lambda_{bed}}{n_b(1-k_b)}\ \text{ohms}\qquad(3)$$

$$X_{aDd}=\frac{8fL(Nk_w)^2}{10^8P}\lambda_aC_{d1}\ \text{ohms}\qquad(4)$$

$$X_{DDd}=X_{LDd}+X_{aDd}\ \text{ohms}\qquad(5)$$

$$R_{Dd}=\frac{8(Nk_w)^2}{P}\frac{r_{bed}}{n_b(1-k_b)}\text{ohms}\qquad(6)$$

$$X_{LDq}=\frac{8fL(Nk_w)^2}{10^8P}\frac{2\pi\lambda_{beq}}{n_b(1+k_b)}\text{ ohms} \quad (7)$$

$$X_{aDq}=\frac{8fL(Nk_w)^2}{10^8P}\lambda_aC_{q1}\text{ ohms} \quad (8)$$

$$X_{DDq}=X_{LDq}+X_{aDq}\text{ ohms} \quad (9)$$

$$R_{Dq}=\frac{8(Nk_w)^2}{P}\frac{r_{beq}}{n_b(1+k_b)} \quad (10)$$

EQUATIONS FOR FIELD-WINDING REACTANCES REFERRED TO STATOR SIDE

In Appendix V, the following equations are derived for mutual and self-reactances of the field winding. These are given by

$$X_{afd}=X_{fDd}=X_{aDd}\text{ ohms} \quad (11)$$

$$X_{ffd}=\frac{8fL(Nk_w)^2}{10^8P}\left(\frac{C_{d1}}{C_1}\right)^2\left(2C_p\lambda_a+\frac{4}{\pi}\lambda_F\right)\text{ ohms} \quad (12)$$

EQUATIONS FOR TRANSIENT AND SUBTRANSIENT REACTANCES

By operational calculus methods[4] it can be shown that the equations for transient and subtransient reactances of synchronous machines with one damper-winding circuit in each axis in addition to the field winding are given by

$$x_d'=x_{Ld}+x_{ad}-\frac{m}{2}\frac{X_{afd}^2}{X_{ffd}} \quad (13)$$

$$x_d''=x_{Ld}+x_{ad}-\frac{m}{2}\times\frac{X_{DDd}X_{afd}^2-2X_{aDd}X_{afd}X_{fDd}+X_{ffd}X_{aDd}^2}{X_{DDd}X_{ffd}-X_{fDd}^2} \quad (14)$$

$$x_q'=x_q''=x_{Lq}+x_{aq}-\frac{m}{2}\frac{X_{aDq}^2}{X_{DDq}} \quad (15)$$

Now if values of X_{LDd}, X_{aDd}, X_{DDd}, X_{afd}, X_{fDd}, and X_{ffd} from equations 3, 4, 5, 11, and 12 are substituted in the definitions of direct-axis transient and subtransient reactances given by equations 13 and 14, then the following expressions are obtained

$$x_d'=x_{Ld}+x_{ad}\left(1-\frac{\lambda_aC_1^2/C_{d1}}{2C_p\lambda_a+\frac{4}{\pi}\lambda_F}\right)\text{ohms} \quad (16)$$

$$x_d''=x_{Ld}+x_{ad}\times\frac{2\pi\lambda_{bed}\left[(2C_p-C_1^2/C_{d1})\lambda_a+\frac{4}{\pi}\lambda_F\right]}{[\lambda_aC_{d1}n_b(1-k_b)+2\pi\lambda_{bed}]\left[(2C_p-C_1^2/C_{d1})\lambda_a+\frac{4}{\pi}\lambda_F\right]+2\pi\lambda_{bed}\lambda_aC_a^2/C_{d1}}\text{ ohms} \quad (17)$$

And if values of X_{LDq}, X_{aDq}, and X_{DDq} from equations 7, 8, and 9 are substituted in the definition of quadrature-axis transient and subtransient reactances given by equation 15, then the following expression is obtained

$$x'_q=x''_q=x_{Lq}+x_{aq}\frac{2\pi\lambda_{beq}}{\lambda_aC_{q1}n_b(1+k_b)+2\pi\lambda_{beq}}\text{ ohms} \quad (18)$$

Appendix I. Nomenclature

B_{ad} = amplitude of space fundamental component of air-gap flux density due to fundamental component of mmf due to current in phase A when its magnetic axis is in line with the pole center

B_{Dd} = amplitude of space fundamental component of air-gap flux density due to fundamental component of mmf due to equivalent single-circuit damper winding in the direct axis

B_{fd} = amplitude of space fundamental component of air-gap flux density due to field winding mmf

C_{d1} = ratio of the amplitude of the fundamental air-gap flux density produced by a sinusoidally distributed mmf whose axis is in line with pole center to that which would be produced with a uniform air gap equal to the effective air gap over the pole center[5]

C_{q1} = corresponding coefficient for the quadrature axis[5]

C_1 = ratio of the fundamental to the actual value of field form at pole center[5]

C_p = ratio of average to value of the field form at pole center[5]

D = stator core bore, inches

D_r = rotor diameter, inches

e_m = amplitude of terminal voltage per phase

e_d = direct-axis armature voltage[1]

e_q = quadrature-axis armature voltage[1]

f = supply frequency in cycles per second

g_e = equivalent air gap under pole center, inches

i_a = instantaneous current of phase A

i_d = direct-axis armature current[1]

i_q = quadrature axis armature current[1]

I_{Dd} = instantaneous current of equivalent single damper winding in the direct axis

I_{Dq} = instantaneous current of equivalent single damper winding in the quadrature-axis

I_f = instantaneous field current

$k_b = \sin n_b\alpha_b/n_b \sin \alpha_b$ (see equations 57 and 61)

k_w = stator winding factor for fundamental components, includes pitch, distribution, and skew factors

k_{Dd}, k_{Dq} = breadth factors for equivalent single-circuit damper windings in the direct and the quadrature axis respectively[8]

$$k_{Dd}=\frac{\sin^2 N_{Dd}\frac{\alpha_b}{2}}{N_{Dd}\sin\frac{\alpha_b}{2}}\text{ for even } n_b,\ N_{Dd}=1/2n_b$$

$$k_{Dd}=\frac{\sin\left(N_{Dd}\frac{\alpha_b}{2}\right)\sin(N_{Dd}+1)\frac{\alpha_b}{2}}{N_{Dd}\sin\frac{\alpha_b}{2}}\text{ for odd } n_b,\ N_{Dd}=1/2(n_b-1)$$

$$k_{Dq}=\frac{\sin n_b\frac{\alpha_b}{2}}{2n_b\sin\frac{\alpha_b}{2}}\text{ for even or odd } n_b$$

k_f = field-winding breadth factor for fundamental component of flux density distribution in the air gap. See equation 104

L = core length, inches

L_d'', L_q'' = subtransient inductances in direct and quadrature axis respectively

L_d, L_q = synchronous inductances in direct and quadrature axis respectively

L_{DDd}, L_{DDq} = self-inductances of equivalent single-circuit damper winding in the direct and quadrature axis respectively

L_{aDd}, L_{aDq} = amplitude of mutual inductances, between phase A and direct and quadrature axis equivalent damper windings

m = number of phases = 3 for 3-phase winding

M_a = amplitude of fundamental component of armature mmf, due to current in phase A

M_{Dd}, M_{Dq} = amplitude of fundamental component of mmf of equivalent damper windings in direct and quadrature axis respectively

M_f = field winding mmf = I_fN_f

N = number of stator series turns per phase

N_f = number of field series turns per pole

n_b = number of damper bars per pole

n = rpm

P = number of poles

$p=\dfrac{d}{dt}$

Q_2 = number of rotor bars

R_{Dd}, R_{Dq} = resistance of equivalent single-circuit damper windings in direct and quadrature axis respectively referred to stator side

R_f = field resistance referred to stator side

r = stator resistance per phase

r_{be} = equivalent single-bar resistance including end ring effect

s = slip

t = time, seconds

T = asynchronous average torque

x_d'', x_q'' = direct- and quadrature-axis subtransient reactances per phase respectively

x_d', x_q' = direct- and quadrature-axis transient reactances per phase respectively

x_d, x_q = direct- and quadrature-axis synchronous reactances per phase respectively

x_{Ld}, x_{Lq} = direct- and quadrature-axis leakage reactances per phase respectively

X_{LDd}, X_{LDq} = direct- and quadrature-axis equivalent single-circuit damper leakage reactances referred to stator side

X_{DDd}, X_{DDq} = direct- and quadrature-axis self-reactances of equivalent single-circuit damper windings referred to stator side

X_{aDd}, X_{aDq} = amplitude of mutual reactances between the windings of phase A and the equivalent single-circuit direct- and quadrature damper windings respectively, referred to stator side

x_{ad}, x_{aq} = direct- and quadrature-axis armature reaction synchronous reactances respectively

x_{be} = equivalent single-bar reactance = $2\pi f\lambda_{be}L10^{-8}$ (2); subscripts d and q refer to direct and quadrature axis respectively

$\alpha_d = \frac{\omega R_{Dd}}{X_{DDd}}$, $\alpha_q = \frac{\omega R_{Dq}}{X_{DDq}}$ (See equations 24 and 25)

δ = angle in electrical degrees between magnetic axis of phase A and rotor direct axis

$\theta = \omega t + \delta$

θ_n = angle between n-n bars (electrical degrees)

λ_{be} = equivalent single bar leakage permeance including end ring effects,[3] per inch; subscripts d and q refer to direct and quadrature axis respectively

$\lambda_a = \frac{6.38D}{Pg_e}$ (see reference 5)

λ_p = pole leakage flux linkage permeance due to body and tip[5] per inch

ψ_d, ψ_q = flux linkages in direct and quadrature axis respectively[1]

$\omega = 2\pi f$

α_b = angle between two bars (uniform distribution of bars)

τ = pole pitch

τ_n = distance between n-n bars

Appendix II. Development of Torque Equation of Unexcited Synchronous Machine at Any Slip s from 2-Reaction Theory

Based on the generalized 2-reaction theory presented by Park[1] with an equivalent 1-rotor circuit in each rotor axis, the following fundamental relations are obtained

$$e_d = -e_m \sin\delta = p\psi_d - ri_d - \psi_q p\theta \qquad (19)$$

$$e_q = e_m \cos\delta = p\psi_q - ri_q + \psi_d p\theta \qquad (20)$$

For no field excitation ψ_d and ψ_q are given by

$$\psi_d = -\frac{\alpha_d L_d + pL_d''}{\alpha_d + p}\, i_d \qquad (21)$$

$$\psi_q = -\frac{\alpha_q L_q + pL_q''}{\alpha_q + p}\, i_q \qquad (22)$$

where

$$p = \frac{d}{dt} \qquad (23)$$

$$\alpha_d = \frac{R_{Dd}}{L_{DDd}} \qquad (24)$$

$$\alpha_q = \frac{R_{Dq}}{L_{DDq}} \qquad (25)$$

$$L_d'' = L_d - \frac{\frac{m}{2} L_{aDd} L_{Dad}}{L_{DDd}} \qquad (26)$$

$$L_q'' = L_q - \frac{\frac{m}{2} L_{aDq} L_{Daq}}{L_{DDq}} \qquad (27)$$

At any slip s,

$$\delta = -s\omega t \qquad (28)$$

$$p\theta = (1-s)\omega \qquad (29)$$

QUADRATURE AXIS
DIRECT AXIS

Fig. 1. Pulsating sinusoidally distributed space flux density with magnetic axis in line with direct axis (pole center), or quadrature axis (interpole center)

And if complex quantities are used, then

$$p = j\omega s \qquad j = \sqrt{-1} \qquad (30)$$

$$e_d = je_m \qquad (31)$$

$$e_q = e_m \qquad (32)$$

Also, the average torque[1] will be given by

$$T = \frac{m}{8} P(i_q\psi_d - i_d\psi_q) \text{ watt-seconds} \qquad (33)$$

Now, if values of ψ_d and ψ_q from equations 21 and 22 are substituted in equations 19 and 20, and if, next, equations 29 through 32 are used, and since for uniform air gap and continuous damper winding the direct- and quadrature-axis constants are identical, then i_d and i_q will be given by

$$i_d = e_m \frac{\omega s - j\alpha_d}{(r\alpha_d - s\omega x_d'') + j(s\omega r + \alpha_d x_d)} \qquad (34)$$

$$i_q = -ji_d \qquad (35)$$

Substituting values of i_d and i_q from equations 34 and 35 into equations 21 and 22 respectively, then using the results in equation 33, the following torque equation is given for the induction motor

$$T = \frac{m}{4} Pe_m^2 \frac{-s\alpha_d(x_d - x_d'')}{(r\alpha_d - s\omega x_d'')^2 + (s\omega r + \alpha_d x_d)^2} \text{ watt-seconds} \qquad (36)$$

Torque has negative sign for motor action.

Now, by inserting the definitions of α_d and x_d'' as given by equations 24 and 26 into equation 36, and arranging terms, it follows that

$$T = \frac{mPe_m^2}{4\omega} \times \frac{-\left(\frac{m}{2}R_{Dd}\right)x_{ad}\left(\frac{m}{2}sX_{aDd}\right)}{\left[r\left(\frac{m}{2}sX_{DDd}\right) + \left(\frac{m}{2}R_{Dd}\right)x_d\right]^2 + \left[x_{Ld}\left(\frac{m}{2}sX_{aDd}\right) + \left(\frac{m}{2}sX_{LDd}\right)x_d - r\left(\frac{m}{2}R_{Dd}\right)\right]^2} \text{ watt-seconds} \qquad (37)$$

Equation 37 is identical with induction motor torque equation as obtained from circuit theory[3] if the identities given by equations 38 through 45, inclusive, are noted, and if the eddy current and hysteresis losses are neglected and unit of torque taken as watt-seconds.

$$V = e_m/\sqrt{2} \qquad (38)$$

$$r_1 = r \qquad (39)$$

$$x_1 = x_{Ld} \qquad (40)$$

$$r_2' = \frac{m}{2}R_{Dd} \qquad (41)$$

$$x_2' = \frac{m}{2}X_{LDd} \qquad (42)$$

$$x_m = x_{ad} = \frac{m}{2}X_{aDd} \qquad (43)$$

$$x_1 + x_m = x_{Ld} + x_{ad} = x_d \qquad (44)$$

$$x_2' + x_m = \frac{m}{2}X_{LDd} + X_{aDd} = \frac{m}{2}X_{DDd} \qquad (45)$$

Appendix III. Amplitude of Fundamental Component of Sinusoidal Mmf Distribution for Each Equivalent Single-Circuit Damper Winding in Direct and Quadrature Axis

If a pulsating sinusoidally distributed space flux density with its magnetic axis in line with the direct axis (pole center) is assumed (Fig. 1), then the currents induced in each two damper bars, located symmetrically with respect to the flux wave axis, are of equal magnitude and of opposite direction[6,8]. The currents of maximum magnitude are induced in the two damper bars that would be located one-half pole pitch from the flux wave axis. The current in each other two damper bars located at an electrical angle $= \theta/2$ from the flux wave axis will have a magnitude equal to $\sin\theta/2$ times the maximum magnitude.

Now, if the current of maximum magnitude be denoted by I_{Dd}, then the current in the 1-to-1 circuit is given by

$$I_{1d} = I_{Dd} \sin \frac{\theta_1}{2} \tag{46}$$

Similarly, the current in any n-n circuit is given by

$$I_{nd} = I_{Dd} \sin \frac{\theta_n}{2} \tag{47}$$

Now, consider the rectangular mmf wave produced by the two damper bars of the 1-to-1 circuit. The amplitude of this rectangular mmf wave is I_{1d}. By Fourier series the amplitude of the fundamental component is given by

$$M_{1d\max} = \frac{4}{\pi} I_{1d} \sin \frac{\theta_1}{2} \text{ ampere turn per pole} \tag{48}$$

The mmf of other pairs of bars symmetrically located with respect to the pole axis can be treated similarly.

The amplitude of the resultant space fundamental mmf of all pairs of bars in ampere turns per pole is given by

$$M_{Dd} = \frac{4}{\pi}\left(I_{1d} \sin \frac{\theta_1}{2} + I_{2d} \sin \frac{\theta_2}{2} + \ldots + I_{NDd} \sin \frac{\theta_{NDd}}{2} \right) \tag{49}$$

Substituting values of I_{1d}, $I_{2d} \ldots I_{nd} \ldots$ from equations 46 and 47, etc., and arranging terms, then

$$M_{Dd} = \frac{2}{\pi} I_{Dd} N_{Dd} (1 - A_{Dd}) \tag{50}$$

where, in general

$$A_{Dd} = \frac{1}{N_{Dd}} (\cos \theta_1 + \cos \theta_2 + \ldots + \cos \theta_n + \ldots + \cos \theta_{NDd}) \tag{51}$$

and

$$\theta_n = \frac{\tau_n}{\tau} \pi \tag{52}$$

If the case of uniform space location of damper bars along the pole face is considered, then for even number of bars per pole the following relations are true

$$n_b = 2N_{Dd} = \text{even number} \tag{53}$$

$$\theta_1 = \alpha_b,\ \theta_2 = 3\alpha_b \ldots \theta_n = (2n-1)\alpha_b \tag{54}$$

And for the odd number of bars

$$n_b = 2N_{Dd} + 1 = \text{odd number} \tag{55}$$

$$\theta_1 = 2\alpha_b,\ \theta_2 = 4\alpha_b \ldots \theta_n = 2n\alpha_b \tag{56}$$

Now if equations 53 and 54, or 55 and 56 are used in equation 51, and the resultant finite trigonometric summation evaluated and then substituted in equation 50, the following expression for M_{Dd} is obtained for both cases of even and odd number of bars per pole

$$M_{Dd} = \frac{1}{\pi} n_b I_{Dd} \left(1 - \frac{\sin n_b \alpha_b}{n_b \sin \alpha_b} \right) = \frac{1}{\pi} n_b I_{Dd} \times (1 - k_b) \tag{57}$$

By a similar reasoning, the amplitude of the resultant space fundamental mmf of all pairs of bars in the quadrature axis in ampere turns per pole can be derived as follows

$$M_{Dq} = \frac{4}{\pi}\left(I_{1q} \cos \frac{\theta_1}{2} + I_{2q} \cos \frac{\theta_2}{2} + \ldots + I_{NDq} \cos \frac{\theta_{NDq}}{2} \right) \tag{58}$$

$$M_{Dq} = \frac{4}{\pi} I_{Dq} \left(\cos^2 \frac{\theta_1}{2} + \cos^2 \frac{\theta_2}{2} + \ldots + \cos^2 \frac{\theta_{NDq}}{2} \right) \tag{59}$$

$$M_{Dq} = \frac{2}{\pi} I_{Dq} \left[N_{Dq} + \frac{N_{Dq}}{N_{Dq}} (\cos \theta_1 + \cos \theta_2 + \ldots + \cos \theta_{NDq}) \right] \tag{60}$$

And if equations 53 and 54 or 55 and 56 are used in the same manner as in deriving equation 57, the following expression is obtained for M_{Dq} for both cases of even and odd numbers of bars per pole.

$$M_{Dq} = \frac{1}{\pi} n_b I_{Dq} \left(1 + \frac{\sin n_b \alpha_b}{n_b \sin \alpha_b} \right) = \frac{1}{\pi} n_b I_{Dq} (1 + k_b) \tag{61}$$

(In deriving equation 61 for the case of odd number of bars the effect of the center bar is obtained by taking the average of the two expressions; once neglecting the center bar effect and once considering the whole bar effect.) Notice that in the induction motor case the angle $\alpha_b = \pi / n_b$ and hence, the second term k_b in the brackets of both equations, 57 and 61, reduces to zero.

Appendix IV. Reactances for Each Equivalent Single-Circuit Damper Winding in Direct and Quadrature Axis

The amplitude of the fundamental component of armature mmf due to an equivalent direct-axis damper-winding current circulating in phase A only is given by[3]

$$M_a = \frac{4}{\pi} \frac{Nk_w}{P} i_{Dd} \tag{62}$$

Therefore the amplitude of the fundamental component of flux density B_{ad} due to M_a when the magnetic axis of phase A is in line with the direct axis is given by

$$B_{ad} = \frac{4}{\pi} \frac{Nk_w}{P} i_{Dd} \frac{3.19}{g_e} C_{d1} \tag{63}$$

Similarly, from Appendix III, the fundamental component of flux density B_{Dd} due to M_{Dd} is given by

$$B_{Dd} = \frac{n_b}{\pi} I_{Dd} (1 - k_b) \frac{3.19}{g_e} C_{d1} \tag{64}$$

Now, if the fundamental armature mmf and the equivalent damper winding mmf are to yield equal fundamental flux density distribution when their respective magnetic axes are aligned, then from $B_{ad} = B_{Dd}$ the following current ratio is obtained

$$\frac{I_{Dd}}{i_{Dd}} = \frac{4Nk_w}{Pn_b(1-k_b)} \tag{65}$$

The voltage ratio between phase A and the equivalent single-circuit direct-axis damper winding when the magnetic axis of phase A is in line with the direct axis is given by[3]

$$\frac{e_{Dd}}{E_{Dd}} = \frac{Nk_w}{PN_{Dd}k_{Dd}} \tag{66}$$

From equations 55 and 56, the impedance ratio for the equivalent direct-axis damper winding is given by

$$A_{zDd} = \frac{4(Nk_w)^2}{P^2 N_{Dd} k_{Dd} n_b (1-k_b)} \tag{67}$$

Now, the total leakage flux linkage of the equivalent direct-axis damper winding is given by

$$\begin{aligned} \psi_{LDd} &= P(I_{1d} + I_{2d} + \ldots + I_{nd} + \ldots + I_{NDd}) 2\lambda_{bed} L \\ &= PN_{Dd} k_{Dd} I_{Dd} (2\lambda_{bed} L) \end{aligned} \tag{68}$$

Therefore, from the fundamental definition of reactance as flux linkage pu current, x_{LDd} is obtained as follows

$$x_{LDd} = 2\pi f \frac{\psi_{LDd}}{10^8 I_{Dd}} = PN_{Dd} k_{Dd} (2x_{bed}) \text{ohms} \tag{69}$$

Consequently, if the ratio given by equation 67 is used to refer x_{LDd} given by equation 69 to the stator side, then

$$X_{LDd} = \frac{8(Nk_w)^2}{Pn_b(1-k_b)} x_{bed} \text{ ohms} \tag{70}$$

In Appendix III, it was mentioned that in the case of the induction motor $k_b = 0$, and $x_{bed} = x_{be}$, consequently

$$\frac{m}{2} X_{LDd} = \frac{8(Nk_w)^2}{Pn_b} x_{be} \text{ ohms} = x_2' \tag{71}$$

(See references 2 and 3.)

Also, from equation 63, the flux linkage in the equivalent direct-axis damper winding due to phase A current i_{Dd} is given by

$$\psi_{Dad} = N_{Dd} k_{Dd} Nk_w \frac{4}{\pi} C_{d1} \lambda_a L i_{Dd} \tag{72}$$

Consequently, from the fundamental concept of inductance as flux linkage pu current, and by use of equation 66 for voltage ratio, the amplitude of the mutual reactance X_{Dad} between the equivalent direct-axis damper winding and phase A referred to the stator side will be given by

$$X_{Dad} = 2\pi f \frac{\psi_{Dad}}{10^8 i_{Dd}} \frac{Nk_w}{PN_{Dd}k_{Dd}} = \frac{8fL(Nk_w)^2}{10^8 P} \times C_{d1}\lambda_a \text{ ohms} \tag{73}$$

Alternatively, from equation 64 the flux linkage in phase A due to the current in the equivalent direct-axis damper winding is given by

$$\psi_{aDd} = (1-k_b) n_b Nk_w \left(\frac{1}{\pi} C_{d1} \lambda_a \right) L I_{Dd} \tag{74}$$

Consequently, if the current ratio, equation 65, is used to eliminate I_{Dd} from equation 74, and the fundamental concept of inductance as flux linkage pu current is again applied, then the amplitude of the mutual reactance X_{aDd} between phase A and the equivalent direct-axis damper winding referred to the stator side will be given by

$$X_{aDd}=2\pi f\frac{\psi_{aDd}}{10^8 i_{Dd}}\frac{4Nk_w}{Pn_b(1-k_b)}i_{Dd}$$
$$=\frac{8fL(Nk_w)^2}{10^8 P}C_{d1}\lambda_a=X_{Dad}\text{ ohms} \qquad (75)$$

Equations 73 and 75 show that the amplitude of the mutual reactances between any phase and the equivalent direct-axis damper winding calculated from either side are equal. Also, since C_{d1} goes to unity for the induction motor case, then

$$\frac{m}{2}X_{aDd}=\frac{m}{2}X_{Dad}=x_{sd}=x_m{}^{2,3} \qquad (76)$$

By reasoning similar to that used in deriving equations 73 and 75, it can be shown that the self-reactance of the equivalent direct-axis damper winding referred to the stator side will be given by

$$X_{DDd}=\frac{2\pi fL}{10^8}\frac{4(Nk_w)^2}{P^2N_{Dd}k_{Dd}n_b(1-k_b)}\times$$
$$\left[Pn_b(1-k_b)N_{Dd}k_{Dd}\left(\frac{1}{\pi}C_{d1}\lambda_a\right)+\right.$$
$$\left.PN_{Dd}k_{Dd}2\lambda_{bed}\right]=\frac{8fL(Nk_w)^2}{10^8P}\times$$
$$\left[\lambda_aC_{d1}+\frac{2\pi\lambda_{bed}}{n_b(1-k_b)}\right]\text{ohms} \qquad (77)$$

The loss in the damper winding

$$P_{Dd}=2r_{bed}I_{Dd}{}^2\left(\sin^2\frac{\theta_1}{2}+\sin^2\frac{\theta_2}{2}+\ldots+\right.$$
$$\left.\sin^2\frac{\theta_{NDd}}{2}\right)P\text{ watts} \qquad (78)$$

By the use of relations given in Appendix III it will be seen that for both odd or even numbers of bars per pole, equation 78 will reduce to

$$P_{Dd}=1/2r_{bed}I_{Dd}{}^2n_b(1-k_b)P\text{ watts} \qquad (79)$$

Now, if the current ratio given by equation 65 is used to replace I_{Dd} by its equivalent i_{Dd} in the stator side, then

$$P_{Dd}=\frac{8(Nk_w)^2}{Pn_b(1-k_b)}i_{Dd}{}^2r_{bed}\text{ watts} \qquad (80)$$

Therefore, from equation 80 the equivalent direct-axis damper-winding resistance referred to the stator side R_{Dd} is given by

$$R_{Dd}=\frac{8(Nk_w)^2}{Pn_b(1-k_b)}r_{bed}\text{ ohms} \qquad (81)$$

Notice the similarity of equation 81 for the reflected resistance with equation 70 for reflected leakage reactance. Equation 81 was obtained from the argument that the reflected resistance R_{Dd} must be such as to have the same heat loss as that of the real damper winding.

Also, for the case of induction motor $k_b=0$, and again

$$\frac{m}{2}R_{Dd}=\frac{4m(Nk_w)^2}{Pn_b}r_{be}=r_2' \qquad (82)$$

(See references 2 and 3.)

Appendix V. Field-Winding Constants

The amplitude of the fundamental component of flux density B_{fd} due to M_{fd} is given by reference 5

$$B_{fd}=N_fI_f\frac{3.19}{g_e}C_1 \qquad (83)$$

Now if B_{fd} is equated to its armature phase and its damper-winding equivalents respectively, and treated in a similar manner to that given in Appendix IV, then the current ratios between field and armature and field and damper respectively are given by

$$\frac{I_f}{i_{fa}}=\frac{4}{\pi}\frac{C_{d1}}{C_1}\frac{Nk_w}{PN_f} \qquad (84)$$

$$\frac{I_f}{I_{fDd}}=\frac{1}{\pi}\frac{C_{d1}}{C_1}\frac{n_b(1-k_b)}{N_f} \qquad (85)$$

Also, from Appendix III it can easily be seen that for the same amplitude of the fundamental component of direct-axis flux density B_d, the voltage ratio between phase A, the equivalent direct-axis damper winding and the field is given respectively by

$$\frac{e_{fd}}{E_{fd}}=\frac{Nk_w}{PN_fk_f} \qquad (86)$$

$$\frac{E_{fDd}}{E_{fd}}=\frac{N_{Dd}k_{Dd}}{N_fk_f} \qquad (87)$$

From equations 84 and 86, the impedance ratio for the field winding is given by

$$A_{zf}=\frac{\frac{4}{\pi}C_{d1}}{C_1k_f}\frac{(Nk_w)^2}{P^2N^2_f} \qquad (88)$$

Again by similar consideration to those given in Appendix IV, the flux linkage in the field winding, due to current in phase A when the direct axis is in line with magnetic axis of phase A, is given by

$$\psi_{fad}=N_fk_fNk_w\frac{4}{\pi}C_{d1}\lambda_aLi_a \qquad (89)$$

Consequently, from the fundamental concept of inductance as flux linkage pu current and by use of voltage ratio, equation 86, the amplitude of the mutual reactance X_{fad} between the field winding and phase A referred to the stator side will be given by

$$X_{fad}=2\pi f\frac{\psi_{fad}}{10^8i_a}\frac{Nk_w}{PN_fk_f}=\frac{8fL(Nk_w)^2}{10^8P}C_{d1}\lambda_a$$
$$\text{ohms} \qquad (90)$$

Alternatively, from equation 83, the flux linkage in phase A due to the current in the field winding is given by

$$\psi_{afd}=Nk_wN_fC_1\lambda_aLI_f \qquad (91)$$

Consequently, if the current ratio, equation 84, is used to eliminate I_f from equation 91, and the fundamental concept of inductance as flux linkage pu current is applied, then the amplitude of the mutual reactance X_{afd} between phase A and the field winding referred to the stator winding will be given by

$$X_{afd}=2\pi f\frac{\psi_{afd}}{10^8i_{fa}}\frac{4}{\pi}\frac{C_{d1}}{C_1}\frac{Nk_w}{PN_f}i_{fa} \qquad (92)$$
$$=\frac{8fL(Nk_w)^2}{10^8P}C_{d1}\lambda_a=X_{fad}\text{ ohms}$$

Equations 90 and 92 show that the amplitude of mutual reactances between any phase and the field winding derived from either side and referred to stator side are equal. Also, it is readily seen that

$$\frac{m}{2}X_{afd}=\frac{m}{2}X_{fad}=x_{ad}\text{ ohms} \qquad (93)$$

By similar reasoning to that used in deriving equations 90 and 92, and if the impedance ratio equation 88 is used, it can be shown that the self-reactance of the field winding referred to stator winding is given by

$$X_{ffd}=\frac{8fL(Nk_w)^2}{10^8P}\frac{C_{d1}}{C_1k_f}\left(\frac{\pi}{2}C_p\lambda_a+\lambda_p\right)\text{ohms}$$
$$(94)$$

Again, from equation 83, the flux linkage in the equivalent direct-axis damper winding due to field current is given by

$$\psi_{Dfd}=PN_fN_{Dd}k_{Dd}C_1\lambda_aLI_f \qquad (95)$$

Consequently, if equation 84 is used to eliminate I_f from equation 95 and then the voltage ratio given by equation 66 is used to refer the quantity ψ_{Dfd} to the stator side and the definition of inductance is applied, then the mutual reactance X_{Dfd} between the equivalent direct-axis winding and the field winding referred to the stator winding is given by

$$X_{Dfd}=\frac{2\pi f}{10^8}\frac{\psi_{Dfd}}{i_{fa}}\frac{4}{\pi}\frac{C_{d1}}{C_1}\frac{Nk_w}{PN_f}\frac{i_{fa}}{I_f}\frac{Nk_w}{PN_{Dd}k_{Dd}}$$
$$=\frac{8fL(Nk_w)^2}{10^8P}C_{d1}\lambda_a\text{ ohms} \qquad (96)$$

By similar reasoning, it can be shown that by using equation 64, the flux linkage in the field winding due to the equivalent direct-axis damper winding is given by

$$\psi_{fDd}=PN_fk_f\frac{1}{\pi}n_b(1-k_b)C_{d1}\lambda_aLI_{Dd} \qquad (97)$$

and in the same manner, if equations 65 and 86 are used to refer the quantity to the stator side, and the definition of inductance is applied, the mutual reactance X_{fDd} between the field winding and the equivalent direct-axis damper winding referred to the stator winding is given by

$$X_{fDd}=\frac{2\pi f}{10^8}\frac{\psi_{fDd}}{i_{Dd}}\frac{4Nk_wi_{Dd}}{Pn_b(1-k_b)I_{Dd}}\frac{Nk_w}{PN_fk_f}$$
$$=\frac{8fL(Nk_w)^2}{10^8P}\lambda_aC_{d1}=X_{Dfd}\text{ ohms} \qquad (98)$$

Equations 96 and 98 show that the mutual reactances between the field winding and the equivalent direct-axis damper winding derived from either side and referred to stator side are equal. Further, it is readily seen that

$$\frac{m}{2}X_{fDd}=\frac{m}{2}X_{Dfd}=x_{ad} \qquad (99)$$

The loss in the field winding

$$P_f=r_fI_f{}^2\text{ watts} \qquad (100)$$

Now, if the current ratio given by

equation 84 is used to replace I_f by its equivalent i_{fu} in the stator side, then

$$P_f=\left(\frac{4}{\pi}\frac{C_{d1}}{C_1}\frac{Nk_w}{PN_f}\right)^2 i_{fu}^2 r_f \text{ watts} \qquad (101)$$

Since the equivalent field-winding resistance R_f referred to the stator side must be such as to have the same heat loss as that of the real field winding, then

$$R_f=\left(\frac{4}{\pi}\frac{C_{d1}}{C_1}\frac{Nk_w}{PN_f}\right)^2 r_f \text{ ohms} \qquad (102)$$

Equation 102 gives the following impedance ratio from energy consideration

$$A_{zf}=\left(\frac{4}{\pi}\frac{C_{d1}}{C_1}\frac{Nk_w}{PN_f}\right)^2 \qquad (103)$$

By comparing equations 103 and 88 the following relation for k_f should hold if the reflected loss is based only on the fundamental component of space flux densities due to I_f or its reflected phase equivalent

$$k_f=\frac{\pi}{4}\frac{C_1}{C_{d1}} \qquad (104)$$

◆

Discussion

Dean Harrington (General Electric Company, Schenectady, N. Y.): Earlier papers form a set of classical references which pioneered in penetrating the mysteries of synchronous machine behavior. Because each considered a different facet of the problem various approaches, definitions and symbols were used. While this was adequate at the time, there is a need for a reliable and consistent present-day treatment requiring a minimum of previous reader knowledge of the subject. This paper which presents reactances in ohmic value, is a good start in this direction.

The literature had developed the concept of nonreciprocal mutual reactance between the polyphase armature and each of the many rotor circuits. In this concept, the rotor sees the mmf of the several phases of the armature. One phase of the armature, however, sees only the current of the particular rotor circuit of interest. The author has nicely avoided this confusing issue by always referring to mutual reactance between one direct-axis phase and the rotor. Since reactances are quoted and used in pu, the conversion from ohms to pu should, for completeness, be covered in Part II of this paper, or good references should be given.

The paper offers several equations for machine torque expressed in watt-seconds. While watt-seconds have the same basic units as pound-feet, nevertheless the former is generally construed as a unit of work while the pound-foot is universally accepted as a unit of torque. If metric units are preferred, the newton-meter is commonly accepted for torque. Mr. Talaat's paper should be a help to the young engineer who is attempting to become acquainted with the elusive ways of synchronous machine reactance.

Lee A. Kilgore (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The author has attempted to improve on the equation for transient and subtransient reactance given 24 years ago (reference 5 of the paper), which is certainly long enough ago to try a new approach. He states that the earlier equation gave results which were too low. It happens that the earlier equation for transient reactance was an exact one if the right permeance values are used and as far as the experience of the writer and his colleagues goes, it has always given accurate results. There have been a number of important water-wheel generator jobs where a low transient reactance was specified, where it was economically profitable to be able to calculate this constant accurately and where it was never found necessary to take any excessive margins to meet the guarantees. The author's equation 16 appears to be identical with that given in the earlier paper, so it may be in the determination of the permeance factors for the field where the author has differed. However, the equation for this quantity is not given. It would be interesting to see a tabulation of test and calculated values such as were given in the original paper.

With regard to the subtransient reactance, the author makes the assumption that the axis components of current in the damper windings are sinusoidally distributed. On the direct axis this seems a particularly poor assumption in many cases. The original paper at least made an attempt to represent the true current distribution in the pole tip bar. This is a point where some further work would seem justified, since no method short of that in Linville's paper (reference 6 of the paper) has attempted to be complete, and that method is too involved for ordinary use. Again the writer's experience with the early equation has been very good with the exception of its application to synchronous motors with very high resistance damper windings where the apparent subtransient reactance on test is higher than calculated because even in one-half cycle the induced current in the outer damper has decayed appreciably and the oscillograms do not show this high decrement term in the subtransient reactance. Possibly the assumption of a sinusoidal current would fit this case better, but would not fit a low-resistance damper. The author states that the paramount criterion for the correctness of the equations are that they reduce to the conventional values for a round rotor machine. This would be desirable but certainly not the major factor, since no salient pole machine approaches a round rotor machine in this respect. Again, it would be interesting to see some test data and to know the damper bar size and resistivity.

I believe the author's approach has more value in calculating constants for synchronous motor starting than for subtransient reactance. I have used such a method, but even for this purpose widely different impedances of damper bars could lead to serious error and call for special treatment.

M. E. Talaat: I agree with Mr. Harrington that the usual unit of torque is the pound-foot; or the newton-meter in the meter-kilogram-second system of units. However, when torque is considered as the product of flux linkage and current, and when it is noted that flux linkage has the unit of volt-second and current has the unit of ampere, their product is in watt-seconds. Multiply torque in watt-seconds by 0.7376 to obtain the result in pound-feet. The watt-second is equal to the newton-meter and the conversion factor is 1.

As to the per-unit system, it is usually agreed to refer machine reactances to their unit impedance in ohms which is machine-rated phase voltage divided by rated phase current. Any reactance given in ohms and referred to the stator side can therefore be divided by this unit impedance in ohms to give the per-unit value based on machine-rated kva and voltage. In network analyzer studies made on large systems it is often found necessary to refer machines' reactances as well as transformers' and transmission lines' impedances on a common kva and voltage base, and further conversions become desirable. Reference 1 of this discussion is a good treatment of the subject.

I agree with Mr. Kilgore that equation 16 for the direct-axis transient reactance in the paper is identical in form with that given in the earlier paper. (See reference 5 of the paper.) If in searching for the truth by the use of a new approach the same equation as the old one is arrived at, then at least we know that our equation is correct in form and by the process of elimination should look for other possible sources of discrepancies between tested and calculated values. Such may be the permeance factors for the field or those entering in the calculation of the stator leakage permeances. As mentioned in the paper these points will be brought out in Part II, to follow.

However, I cannot agree with Mr. Kilgore that the subtransient reactance is a truer assumption of the current distribution in the bars than that made in the paper. The coefficient (reference 5 of the paper) $\cos (n^1-1)\tau_b/\tau_r\ \pi/2$ if examined for the case of the induction motor where $n_b = \tau_r/\tau_b$ would go to

$$\cos\left(\frac{\pi}{2}-\frac{\tau_b}{\tau_r}\frac{\pi}{2}\right)=\sin\frac{\tau_b}{\tau_r}\frac{\pi}{2}\approx\frac{\tau_b}{\tau_r}\frac{\pi}{2}$$

Since, for the induction motor the field leakage permenance λ_F goes to infinity and (reference 5 of the paper)

$$6.38\left(0.5+\frac{h_{b2}}{b_{b2}}+\frac{h_{b1}}{3b_{b1}}\right)=6.38F_b$$

represent twice the permeance per bar, then his

$$\lambda_{Dd}=\frac{\tau_b}{\tau_r}\frac{\pi}{2}6.38F_b=10\frac{\tau_b}{\tau_r}F_b$$

while his λ_{Dq} is taken to be actually that of the induction motor and is given (reference 5 of the paper) as

$$\lambda_{Dq}=20\frac{\tau_b}{\tau_r}F_b$$

where F_b is taken here for brevity to mean the leakage permeance factor per bar. This means that by Mr. Kilgore's paper

$$X_{Dd}'=\frac{1}{2}X_{Dq}'$$

for the case of the induction motor.

This shows that Mr. Kilgore's treatment of the damper winding case fails to meet the paramount criterion for the correctness of the equation of X_{Dd} (reflected damper winding leakage reactance in the direct axis), namely, that for the case of continuous damper and uniform air gap the direct- and quadrature-axis quantities should become equal to one another and identical with the induction motor constant. On the contrary, the quadrature axis reflected secondary reactance in Mr. Kilgore's paper becomes twice that of the direct axis, which is physically inconceivable.

In a typical large water-wheel synchronous machine Mr. Kilgore's $X_{Dd}'=0.069$ (in per-unit of rated phase voltage and rated phase current), and by the new method $X_{Dd}'=0.12$. The subtransient reactance by his method was $x_{du}''=0.175$, and by the new method $X_{Dd}'=0.226$ (using the same stator leakage reactance $=0.106$), while the measured value at 16.5 per cent (%) voltage was 0.217. If for the sake of comparison we accept the tested value at 16.5% voltage to be the correct unsaturated subtransient reactance and the stator leakage reactance to be true at 0.106, this leaves $0.217-0.106=0.111$ for X_{Dd}'. This means an error in Mr. Kilgore's X_{Dd}' of −38% and an error in X_{Dd}' by the new method of only +8%. The error in the subtransient reactance by Mr. Kilgore's method is −18.5% and the error by the new method is only +4%. The calculated unsaturated value should always be slightly higher than any measured value, because of saturation. This accounts for the plus sign in the percentage difference between measured value and that calculated by the new method. The machine given here for comparison had all bars located near the pole face; they all had the same configuration and they all were of copper. The ratio of bar reactance to bar resistance was 26 at 60 cycles and 75 degrees centigrade, and the machine had higher subtransient time constant than normal machines $T_d''=0.087$ second. The large discrepancy between tested value and that calculated by Mr. Kilgore's method cannot be blamed therefore on a high resistance damper winding or on a fast-decaying subtransient current, as he pointed out in his discussion, but lies in a more basic error in his equation, as appears from its failure to be true for the limiting case of the induction motor. The basis on which Mr. Kilgore has taken the factor

$$\cos (n_b-1)\frac{\tau_b}{\tau_r}\frac{\pi}{2}$$

to be the fraction of the armature mmf, acting across the subtransient leakage paths in the rotor was not indicated in his paper. In his tabulation of calculated and tested results, no mention of the test voltages during measurements was given or whether saturation was taken into consideration in his calculations, or how. In Tables I and II of his paper eleven cases out of 19, for machines with damper bars, show higher subtransient reactances by measurement than by calculation. This discrepancy is in the wrong direction since any measured value should be less rather than greater than a calculated value with no saturation taken into account.

It is probable that the measured direct-axis subtransient reactances given in Mr. Kilgore's paper were obtained from tests taken at voltages high enough to give rated current values of direct-axis transient reactances, and therefore yielded fairly saturated values for the subtransient reactances, which made them seem closer to the low values calculated by his method. This, together with the fact that in many cases a large percentage of error in calculating X_{Dd}' reflects in a smaller percentage of error in the calculated direct-axis subtransient reactance, may have been the reason why Mr. Kilgore and his colleagues did not notice the seriousness of the discrepancy between calculated and measured values.

The assumption of sinusoidal space distribution of currents in the bars located in the pole face is based on the following two assumptions:

1. That during disturbance a time-varying sinusoidal space distribution of fundamental air-gap flux density is centered along the magnetic axis of the pole for the case of direct-axis quantities and along the interpolar axis for the quadrature-axis quantities. A pulsating field is, for instance, the case in method 3 of the AIEE test code for synchronous machines[2] for determination of direct-axis subtransient reactance form a static impedance test with single-phase voltage whose magnetic axis is in line with the pole axis.
2. That the impedance per bar, composed of leakage reactance per bar and resistance per bar, is the same for all bars. This assumes that all bars are located in the pole face and have the same configuration. This neglects only the variation in harmonic differential and tooth top leakage permeances due to variations in the air gap, and which are generally small. For pole tip bars which have different configuration a special treatment will be presented in Part II of his paper.

From these two assumptions one can proceed as follows to substantiate the assumption of sinusoidal space distribution of currents in the damper bars. With reference to Fig. 1, the sinusoidally space distributed time varying flux density in the direct-axis is given by $B(x,t)=B_d(t)\cos\frac{\pi}{\tau}x$, or $B(\theta,t)=B_d(t)\cos\theta$ where $\theta=\frac{x}{\tau}\pi$.

The flux linking any two damper bars n-n that are located symmetrically with respect to the flux wave axis is given by

$$\psi_n(t)=L\int_{-\frac{\tau_n}{2}}^{\frac{\tau_n}{2}}B_d(t)\cos\frac{\pi}{\tau}x\,dx$$

$$=\frac{2}{\pi}\tau LB_d(t)\sin\frac{\theta n}{2}$$

where

$$\theta n=\frac{\tau_n}{\tau}\pi$$

Therefore the voltage induced in n-n circuit is given by

$$E_{nd}(t)=\frac{-d\psi_n(t)}{dt}10^{-8}$$

$$=\left(\frac{2}{\pi}\tau L\frac{dB_d(t)}{dt}10^{-8}\right)\sin\frac{\theta n}{2}$$

$$=E_{Dd}(t)\sin\frac{\theta n}{2}$$

Now, from basic principles

$$2r_{be}I_{nd}(t)+2L_{be}\frac{dI_{nd}(t)}{dt}$$

$$=E_{nd}(t)=E_{Dd}(t)\sin\frac{\theta n}{2}$$

Solution of this differential equation yields a current of the form

$$I_{nd}(t)=I_{Dd}(t)\sin\frac{\theta n}{2}$$

where $I_{Dd}(t)$ is the instantaneous current that would be induced in the two bars embracing a full pole pitch, and is the maximum possible current.

From a qualitative point of view, it is known that the basic principles of damping state that maximum damping effect in the direct-axis is given by the outermost bars in the pole face and zero-damping effect by a bar located at the pole center. A sinusoidal space distribution of currents in the damper bars meets this qualitative requirement.

It is therefore clearly seen that the assumption of sinusoidal space distribution of currents in the damper bars is as good an assumption as that of a sinusoidal fundamental space distribution of effective flux density in the air gap, which is one of the basic assumptions made in the development of the 2-reaction theory of synchronous machines.[1]

Gas-Pressurized 120-Kv and 161-Kv Pipe-Type Cables in Ontario

STEPHEN KOZAK
ASSOCIATE MEMBER AIEE

COLIN PRESCOTT
NONMEMBER AIEE

ADDITIONAL power requirements in the Toronto area of the Southern Ontario System led to the construction of the Richard L. Hearn Generating Station. The output of this thermal generating station is taken at 115 kv into the existing system by a 4-circuit overhead line. Where the new 4-circuit line joins the existing network, difficulty was experienced in obtaining rights of way for additional overhead circuits. Underground construction was the only practicable alternative. In 1951, approximately 1 mile of 115-kv pipe-type gas compression cable was installed, followed in 1952 by a further $4^1/_2$ miles of pipe-type cable. Two miles of the latter were of the gas compression type and $2^1/_2$ miles were the Atkinson-Fisher gas-pressurized type. It is with this latter $2^1/_2$ circuit miles that this paper is concerned.

Route

The route length of $1^1/_4$ miles traverses undeveloped land of the Don River basin, Fig. 1. Difficulty in obtaining permanent right of way on the east river bank led to the placing of part of the route on the west bank and necessitated two river crossings. The preliminary investigations of the route can be divided into three parts.

First, the river crossings were selected from several profiles of soundings, utilizing the cone penetrometer method to determine solid bearing underneath the accumulated silt. Fig. 2 is representative, and indicates that unstable bearing extended for approximately 4 feet below normal river bottom. The resultant recommendation of burial at the 237-foot elevation was modified to the 235-foot elevation, when civic authorities revealed an intention to dredge to the 239-foot elevation at some future date.

Second, a soil classification was conducted along the route by sampling at auger holes every 300 feet. A tabulation of soils, hydrogen ion concentration, and presence of free water was prepared. The information obtained was of limited use as actual excavation showed much more frequent variation, and on future projects it will not be pursued.

The third investigation was concerned with soil thermal resistivity. The results obtained by the transient needle method[1] are shown on Fig. 3. In the section from 2,500 to 3,500 feet, the natural undisturbed clay has been covered with as much as 3 feet of trash fill including ashes, bottles, and various metal scrap ranging from bottle caps to bedsteads. The low values on the chart at 3,500 to 4,500 feet are coincident with an underground water course. The high thermal resistivity for the ground surface under Bloor Viaduct at 4,600 feet may be remarked, the bridge effectively shielding the ground from rainfall. Excavation of the heterogeneous fill revealed many air pockets, no doubt partly responsible for the high thermal resistivities. After laying, 2 feet of sand backfill was used in these areas. The remainder was of the original excavation materials, suitably screened.

The minimum required 3-foot depth of cover was maintained wherever possible. However, the vertical approaches to the river crossings, coincident as they were with main railway-line crossing, necessitated much greater depth, as did certain uncharted obstructions. The vertical and horizontal bends were onerous and demanded due consideration in planning the cable pulling. The profile and splicing locations were established in cooperation with the cable manufacturer in the early stages of the project.

Choice of System

A system obtaining great mechanical integrity and yet possessing flexibility was of prime concern. Additionally, in such a relatively short route length, it was of paramount importance to have the land cable suitable for the river crossings. Both direct burial and duct and manhole systems would require special submarine construction. The direct-burial alternative was considered not sufficiently sound mechanically.

City conditions with the attendant likelihood of interference by other underground plant dictated maximum mechanical strength. City conditions also called for maximum flexibility of routing. It was decided that a system employing steel pipe was most adaptable to these conflicting requirements.

In the selection of a pipe-type system, gas-pressurized, gas compression, and high-pressure oil-filled were considered. The first two were similar in first cost and less than the high-pressure oil-filled. The Atkinson-Fisher gas-pressurized pipe-type cable was selected for the section from Gerrard Transformer Station to Bloor Street Junction.

Circuit Requirements and Cable Description

Of the two parallel circuits, one was required to operate on the 60-cycle 120-kv (nominal 115-kv) solidly grounded neutral system, the other to operate temporarily on the 25-cycle 120-kv (nominal 115-kv) system convertible to 60-cycle operation at some future date. The latter system is grounded through a resistance and is considered as ungrounded for the purpose of voltage rating. This circuit was insulated for 161-kv equivalent grounded neutral.[2] For the potheads the 138- and 161-kv classes of the AIEE standard for potheads[3] were selected. Joints were rated to be in accord with cable rating. Both circuits were required to transmit 125 megavolt-amperes at 115 kv, 60 cycles, at a design load factor of 100 per cent (%).

For these conditions of load capacity with all losses considered, a copper conductor size of 1,150,000 circular mils of annular cross section, operating at 85 degrees centigrade (C) maximum conductor temperature, was required for the pipe sections. With sheaths open-circuited, the terminal ends capacity was considerably higher for the same size. The cable dimensions are given in Table I for both 120- and 161-kv designs. For the cables in pipe, the hollow annular conductor of shaped copper segments is insulated with mass-impregnated paper dielectric, protected with bronze, polyethylene and copper tapes, and D-shaped copper skid wire. The three cores are factory cabled, with a length of lay of approximately 48 inches. The decision to cable the cores was influenced by many factors; those of prime importance being as follows:

Paper 55-50, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 22, 1954; made available for printing December 8, 1954.

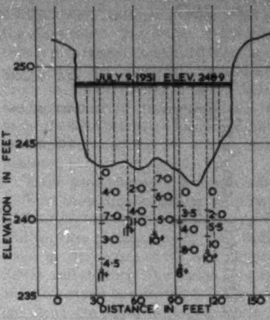

Fig. 2 (right). Profile of typical river crossing. Cone penetrometer readings indicate ultimate bearing capacity in tons per square foot

1. To mitigate end thrust on the joints during load cycles.

2. To contribute to easier pulling and avoid any danger of jamming on relatively short bends.

3. To simplify installation and reel handling, and reduce exposure time to outside atmosphere.

The terminal ends were of the same conductor construction and insulation details but were sheathed with seamless aluminum sheath.

All cables were shipped under nitrogen pressure of 25 to 30 pounds per square inch (psi) in the core; the pipe cables were additionally protected by a gas-tight reel construction. The shipping lengths of pipe cable were dictated by the route access difficulties, river crossings, and horizontal and vertical bends. The 6,000-foot route was supplied in five shipping lengths, between 1,000 and 1,200 feet in length. The pipe route was particularly difficult in respect to bends. At one river crossing vertical bends to reach specified depth were immediately followed by tight right angle horizontal bends (minimum radius 22 feet) to remain within the right of way.

Pipe Cable: Design and Manufacture

The cable design was founded on the principles of gas pressure void control in mass-impregnated paper dielectric. The use of an almost inert gas at high pressure in intimate contact with, and forming part of, the dielectric was first suggested by the Atkinson-Fisher team in their 1925 patents. Wherever possible the design incorporated manufacturing techniques already successfully developed, notably those related to the conventional oil-filled system, and which would realize to the fullest extent the economic and reliable exploitation of these principles. Experimental work on similar cables since 1950 had shown that the criteria of design, available materials and terminations, were suited to this pipe-type Atkinson-Fisher system.

Adoption of a hollow conductor has the advantage that the maximum gas pressure is coincident with the maximum electrical stress at the conductor surface. It permits the use of gas supply through the terminal ends after the fashion of oil-filled system oil feed. It also permits the use of a simple pothead design uncluttered by accessories. Coupled with the use of a tight-fitting, seamless, and pressure-retaining aluminum sheath, it allows a simple design of factory-sealed single-conductor terminal cable which has sensibly the same constructional and electrical characteristics as the cable in the pipe. For the required cross-sectional area, the annular conductor offsets skin effect to a degree comparable to a segmental conductor.

Initially, the insulant thickness for both circuits was chosen to limit the maximum operating stress to 92 kv per centimeter (cm). This premised the use of single annulus of conductor segments; subsequently a 2-layer construction was adopted which increased the conductor diameter approximately 1.5%, resulting in a maximum operating stress of 90 kv per cm.

The maximum radial stress of 92 kv per cm was chosen to provide the following factors of safety:

1. With respect to external surges $\frac{g_{ca}}{g_c} \geqq 8$

2. With respect to internal surges $\frac{g_{ct}}{g_c} \geqq 3$

3. With respect to ionization ignition $\frac{g_{cn}}{g_c} \geqq 2$

where

g_c = radial stress at the conductor surface at rated voltage rms.

g_{ct} = radial stress at the surface of the conductor at the 1-hour abscissa on the voltage-time-to-breakdown curve.

g_{ca} = radial stress at the conductor surface for impulse voltage breakdown (crest value) wherein puncture occurs on the crest or tail of the wave, thus giving minimum breakdown rather than a maximum one which would occur if the value were on the wave front.

g_{cn} = radial stress at the conductor surface at the ionization ignition voltage.

Laboratory development tests on 69-kv cable designed to the same parameters[4] confirm that the design factors of safety with respect to g_{ct}, g_{cn}, and g_{ca} are readily attainable. For an impulse test of 4.5 $(E+10)$ kv, where E is the line-to-line voltage in kv, the corresponding calculated values of radial stress at the conductor surface are 760 kv per cm and 750 kv per cm for 120- and 161-kv cable respectively. Development and type tests have indicated an impulse

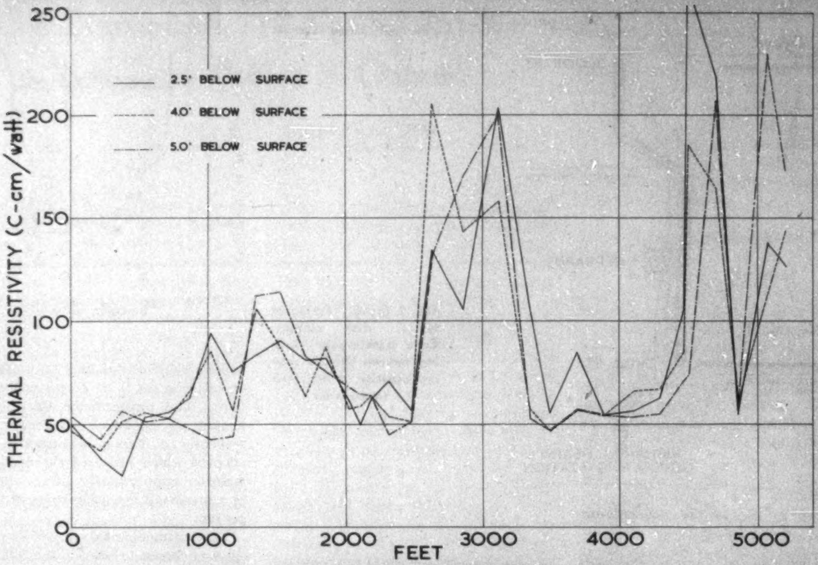

Fig. 3. Soil thermal resistivity determinations along cable route

strength for this cable corresponding to values of g_{ea} of at least 900 kv per cm, and the work of a host of contributors (see references to reference 4) has shown representative values for all high-voltage cables between 800 to 1,000 kv per cm.

The hollow conductor is constructed by utilizing a double layer, each of 16 shaped segments. The double layer had the following advantages over a single construction:

1. Better drawing and stranding when compared to that obtainable with the relatively slender segment of a single layer for this area.
2. The first layer of 850,000 circular mils was a construction used for many miles of conventional oil-filled cable and production techniques were thus in existence.
3. The double layer facilitated the fitting of a flush connector desired in the joint design by the mere removal and scarfing of the outer layer.

The selection of the 0.690-inch gas channel was influenced by item 2 in the foregoing, but included the forethought that the channel must be blown clear of any excess impregnating compound after manufacture. However, in the case of an aluminum-sheathed cable[4] with a 3/8-inch gas channel, manufactured concurrently with the subject cable, no difficulty was experienced in this respect. Unless otherwise dictated, future construction will adopt a 0.5-inch channel.

The shield construction around each core was designed to consist of 1 by 0.004-inch bronze tape intercalated with polyethylene tape; 1 by 0.004-inch bronze intercalated with polyethylene tape; and 1 by 0.070 by 0.200-inch copper skid wire with 1.5-inch lay over-all. During the processing of an experimental length, it was found that the bronze tapes tended to open up when the cores were cabled together, thereby impairing the moisture seal for installation purposes. As installation was to take place during the rainy fall season, it was decided to replace the outer tapes with two intercalated soft copper tapes which would hold down the bronze and polyethylene moisture seal.

Application of the insulant papers followed conventional practice for solid-type cables with additional close attention to paper tape widths and tensions. Superdense, relatively thin papers were

applied next to the conductor for dielectric grading. Approximately 0.050 inch of 0.0025-inch superdense paper was applied, the remainder of the insulant thickness was of 0.005-inch dense papers. Cables were dried and mass-impregnated before skid wire application and cabling (and also before sheathing the single conductor terminal cables). Close attention was paid to the pressure-cooling process to ensure a dielectric as completely saturated as possible. The impregnant was a compound of polyisobutylene and mineral oil having a viscosity of 4,000 Saybolt universal seconds at 50 C and exhibiting an extremely low and stable power factor of 0.03% at 100 C.

Single-Conductor Terminal Ends

This application of aluminum sheath to high internal pressure high-voltage operation is of some interest. The superior performance of aluminum over lead or lead alloy sheathing materials[5,6] in respect to greater strength, hardness, fatigue, and creep resistance is consequently applied to the fullest economical benefit. For example, calculation for the 161-kv terminal ends show that a pressure of 700–1,000 psi is required before a stress corresponding to 0.1% elongation (proof stress) is attained. The aluminum sheath in this case is of 0.135-inch thickness and 2.72-inch outside diameter.

The application of aluminum sheath for the terminal ends was made possible by taking advantage of three developments, as follows:

1. Development of a cast-plumb technique to effect the seal between sheath and pothead and between sheath and trifurcating joint.
2. The application of an asphaltic, rubber-and-fabric tape combination, commonly known as a rubber sandwich, which permits direct burial and sheath isolation.
3. The design of a rugged gas feed pipe-line insulator capable of withstanding 500-psi internal pressure which, coupled with item 2 permitted operation of the terminal end cable with sheaths open-circuited. Adequate current-carrying capacity for the terminal ends was practical only with the sheath currents interrupted.

Terminal Design

The general layout of the terminal design is shown in Fig. 4. The porcelain shell, stainless-steel dome, and cast-plumb body are designed for the full operating pressure of 200 psi. Each pothead assembly was subjected to an acceptance test of 500 psi oil pressure for 6 hours, followed by 300-psi air pressure for 6 days. During experimental work similar porcelains have withstood 500-psi 1/2-hour cycle tests and sustained 300-psi pressures of several weeks' duration.

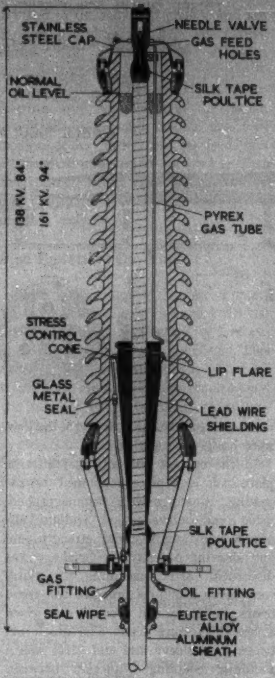

Fig. 4. Terminal design, 138-kv and 161-kv grounded neutral rating at 200-psi internal pressure

The aluminum sheath is sealed to the wiping bell by a cast plumb. First, a small wiped seal is made over asbestos packing between the sheath and bell. This seal is then reinforced by pouring a molten alloy of 63/37 tin-lead at the required temperature into an aluminum mold clamped around the sheath. The act of pouring displaces a hot palm oil flux from the mold.

On installation, the terminal is filled with oil to a predetermined level, such that a gas space is obtained at the top. The gas from the external gas supply is carried through the filling oil by a heavy-wall Pyrex glass tube. Gas is introduced to the conductor hollow core from the gas dome through a needle valve orifice. The proper oil level is realized by allowing heated compound into the bottom of the terminal while vacuum is maintained on the glass tube. The height of the glass tube is so arranged that the oil level, upon contraction to ambient temperature, drops to approximately 8 inches below the top of the tube, thereby effecting the proper balance between a compound-filled terminal and an internal volume compensator.

Design parameters of the stress control cone are those used in designs which have successfully withstood long-time 60-cycle and impulse voltage tests.[4] The radial stress on the surface of the cone for both 138 kv and 161 kv is 7 kv per cm. Longitudinal stresses are limited to 1.5 kv per cm along the stress cone profile and to 5.0 kv per cm in the terminal filling oil adjacent to the stress control cone lip flare. These stresses are in accord with other comparable empirical data.[7] Dimensions imposed on the pothead to provide adequate external flashover values provide adequate internal creepage distance and prove to be approximately three and four times the design stress criteria of 1 kv per cm for the 161-kv and 138-kv designs respectively.

Joints

Joint design was based upon the use of hand-applied preimpregnated straight-paper tapes, similar in density and thickness to the factory-applied cable insulant. They were supplied preimpregnated with cable compound in sealed containers after drying and vacuum treatment. Stepping and taping profiles were calculated by methods according to Short,[8] using the following design parameters:

Radial stress at conductor surface for rated voltage

$g_c = 92$ kv per cm

Radial stress at cable insulant surface for rated voltage

$g_s = 58$ kv per cm for 120-kv cable
$g_s = 49$ kv per cm for 161-kv cable

Radial stress at ferrule surface for rated voltage

g_f between $0.48\ g_c$ and $0.50\ g_c$

Maximum longitudinal stress along stepping profile 1.3 kv per cm.

Maximum longitudinal stress along stress cone profile 1.2 kv per cm.

These criteria result in a design strength of joint, with factors of safety to internal and external transient surges, compatible to that of the cable itself. Since cable geometry is undisturbed by the flush ferrule, the factor of safety in relation to conductor and ferrule surface stresses

may be wholly applied to offset the uncertainties of field jointing

Features of the joint are shown in Figs. 5, 6, and 7. The completed single-conductor joints are supported in cast-aluminum cradles, which are banded with stainless-steel ribbon, spaced apart, and connected by an aluminum channel. This channel allows the joint casing to slide smoothly over the assembly. Originally, it was intended that the joint casing would serve as a temporary cap over the cable ends during the period between pulling and start of jointing, and a somewhat complex system of gasketed flanges was designed. Subsequently, the sleeve proved much too heavy and unwieldy for this purpose, and comparatively light sheet metal caps were used. Skid wires were terminated on binding posts and the posts at each end of the joint were jumpered together.

In the case of trifurcating joint, the plate was a 1-piece machined bronze casting. Castings were gammagraphed, using a radioactive isotope "Iridium 192" of approximately 50 curies' strength, and any showing porosity or shrinkage was discarded. After machining, the plates were given a 500-psi pressure test for 4 hours, surface-tinned over-all, and given a repeat pressure test. The union between joint sleeve and end plate was a Victaulic coupling. Junction between the aluminum-sheathed terminal cables and the end plate was achieved by use of the cast-plumb technique as described for the potheads.

Jointing procedure was similar in many respects to that followed for the conventional low-pressure oil-filled system. In this case, gas instead of oil was kept under a positive pressure within the hollow core and was allowed to flow from it when cut, thus preventing contamination from the atmosphere. To this safeguard was added flushing with hot compound at frequent intervals throughout the jointing. The 1-piece flush ferrule is fitted with a valve enabling the nitrogen to bleed past the soldering operation. Taping over the stepping matched the factory insulating tapes in width, thickness, and density. Once the hand-applied insulation reached the diameter of the factory insulation, wider tapes were applied to speed taping. Wherever and whenever possible, exposed insulation was temporarily wrapped with polyethylene tape to exclude mois-

ture and contaminants. No effort was made to air-condition the joint bays, which were sheeted over and warmed above ambient by electric heat lamps. Almost all operations were kept confined to the joint bay so that exits and entrances were minimized. After completion of the acceptance pressure tests, the joints were directly buried.

Gas Charging and Ancillary Equipment

Both circuits, 120-kv and 161-kv, are supplied from a gas-charging cubicle located at Gerrard Street. Each phase of each circuit is fed through its Gerrard Station terminal by underground gas lines of 3/8-inch outside diameter dehydrated copper tubing, insulated and protected with a 1/16-inch wall of extruded polyethylene. A diaphragm-type valve and a high-pressure pipe-line insulator were interposed at the base of each pothead to maintain isolation of the pothead above ground and to permit control of gas to each terminal.

The insulated gas lines were drawn into conduit embedded in the concrete protective cover over the direct-buried terminal cables. Each line was purged to a dew-point value of −20 degrees Fahrenheit before connection. The steel pipe of each circuit was similarly fed at the Gerrard end at the underground trifurcating joints.

The control panel in the gas-charging cubicle was arranged so that manipulation of valves would enable gas to supply the pipe, each individual hollow core of each phase, or all four together. Fig. 8 depicts the schematic diagram of the gas connections. In normal operation the two stand-by gas bottles are disconnected from the line, and the pressure gauge on the manifold is connected to read the pressure on all three phases. Pressure alarms are connected to the pipe gas feed line and to the manifold phases, and are set for low alarm at 175 psi. These alarms are bourdon-tube actuated mercury switches.

Throughout the panel standard components were specified and the design permitted simple and flexible gas feed manipulation. Individual gas feeds can be isolated and tested for leaks. One disadvantage of the panel design rests in the multiplicity of fittings subject to possible leakage.

Pipe Protective Covering

Since factory-applied protective coatings are customarily expected to be superior to field application, a factory-applied coating was specified. This decision was strengthened by the relatively small amounts of pipe required and the number of route obstructions preventing any degree of continuous field application. Coal tar, Fiberglas reinforced enamel coating was specified as follows:

1. Pipe to be cleaned internally and externally by shot-blasting.
2. Bond coating of coal tar primer.
3. Hot coating, 1/16-inch minimum, coal tar enamel.
4. One wrap 0.015-inch Fiberglas wrap.
5. Hot coating, 1/32-inch minimum, coal tar enamel.
6. One wrap tar impregnated 15-pound asbestos pipe-line felt.
7. One wrap heavy Kraft paper.

A thin spray coating of No-Oxide export no. *2 W* pipe primer was specified for the inside of the pipe. An electrical holiday-detection test was applied at the factory just after coating application, using a spark coil type of detector, producing a maximum voltage of approximately 12 kv. All holidays, which were not numerous at this stage, were repaired.

The pipe was transported to the site of the work by rail, stored for a minimum of two weeks, and distributed direct to the work by truck. Great care was taken at all times to avoid damage to the coating, the pipe being lifted by means of an attachment to each uncoated end. Pipes were plugged at the factory to keep out dirt and water.

The first sections of pipe were welded and made ready for holiday test approximately one month after coating application. Many holidays in the coating were revealed by test—averaging 12 per 40-foot length of 8-inch pipe, and approximately 6 per length of 6-inch pipe. Reduction of the detector output voltage to the minimum value which would arc across a gap in the coating, approximately 5 kv, showed no reduction in the number of indicated holidays.

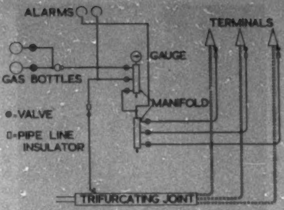

Fig. 8. Schematic diagram: gas-charging controls

Inspection of the holidays revealed some slight signs of mechanical damage: a few hair-line cracks radiating from a central point such as might have been caused by a blow. The remaining holidays coincided with small gas bubbles between the primer and the first enamel coat. Surprisingly, the hand-coated and wrapped joints were consistently the better covering by a wide margin.

It was found that a light blow, for example, a stone weighing 1 pound dropped from about 4 feet, would produce a holiday. The bond between the pipe and the coating was poor. The difference between this bond on the sample prepared for laboratory test and the pipe in the field was most marked. On the former, the enamel could be chipped off only in small flakes with the use of a hammer and chisel; on the latter the pipe could be peeled by hand. Analysis of the coating materials showed no adulteration or evidence of inferiority of the raw materials.

Patching all holidays would have been both expensive and so frequent as to constitute almost a route-long hand-wrapping job. It was decided to abandon electrical holiday detection; to patch the few places where there was obvious mechanical damage, relying on cathodic protection to back up the poor coating.

Subsequent investigations could not isolate any single reason for the poor quality of coating. One possible explanation for the bubbles is the fact that asbestos pipe-line felt has been found to give off volatiles on contact with hot enamel of 500 degrees Fahrenheit.[8] Improper curing of the primer, over-heating, and improper stirring of the enamel are all possible causes, and investigation showed that conditions would allow such occurrences, but not their persistence during coating. Evidence of mishandling

Fig. 9. Laying of 6- and 8-inch pipe in common trench

of the hot pipe immediately after coating on poorly padded racks and rollers was also evident, and could have contributed to numerous holidays, especially where the lengths were allowed to roll together while still warm. Our experience has shown that there is very little tolerance in the application recommendations, and any future job will have to be painstakingly inspected at every step.

Installation

Following pipe placement and welding of sections, Fig. 9, the welds were water-bath tested at 150 to 175 psi. Backfill consisted of a 3-inch layer of sand under and over, a 6-inch layer selected from previously excavated material, followed by machine placement of the remainder.

Advantage was taken of the proximity of the cable manufacturing plant by arranging that no cable was to be ordered on the job site unless conditions favored immediate installation. Prior to a pulling date, joint flanges were welded to each pipe section, tarpaulins erected and pipe sections wired and purged to a dew point of −20 degrees Fahrenheit, with the use of nitrogen of 0.1% oxygen content. The cabled pipe cable was transported on welded steel reels sealed by an impervious laminated gas blanket under the lagging. The large size of reel permitted only a slight positive pressure within the blanket. However, the cable cores were maintained at a positive pressure of 30 to 40 psi during shipment and during pulling operations. The three conductors were fitted with pulling eyes and end seals made gas-tight to the outer tapes by the use of a sleeve filled with low-melt alloy; see Fig. 10.

During pulling in, a nitrogen flow was maintained on the pipe from the end remote from the cable feed, and a slight amount of cable compound was used to aid the pulling in. Actual pulling tensions were not recorded in this installation, as only short lengths were involved (maximum 1,200 feet); however, it is sufficient to say that the pulls in all cases were relatively light, and no disturbance of skid wire or protective tapes was observed.

After completion of pulling in a particular length, the cable cores were blown clear with a grade of nitrogen of high purity, containing less than 0.002% oxygen, excess cable was cut off, and cable ends were capped and jumpered to the nitrogen supply. All operations were performed on the principle of maintaining the cables under pressure and/or gas flow at all times. After capping, and check of cable cores and pipe for dew point, the ends were sealed in nightcaps gasketted to the joint flanges.

Acceptance Tests

After installation was completed, each circuit was subjected to a 12-hour pressure test at 300 psi. A d-c test voltage as outlined in the Association of Edison Illuminating Companies' specifications[2] was applied for 15 minutes after completion of the pressure test. The test voltage for the 120-kv circuit was 203-kv direct current; for the 161-kv circuit the d-c test voltage was 250 kv, limited by the test set and atmospheric conditions.

Anticorrosion Protection

The cable route parallels two trunk railways systems and the installation was followed by the construction of two parallel oil pipe lines. The city street railway system also imposed an involved stray current pattern and it was decided to postpone the choice of a cathodic protection system until construction activity had subsided and a regular pattern of soil potentials had become manifest. The cable pipes were bonded to the station grounds at each terminal. An early survey indicated that a magnesium anode bed near Gerrard might, at least, provide some temporary protection, this was installed but subsequent measurements indicated that it was ineffective.

Pipe-to-soil potentials measured during the first year of service indicated peak pipe potentials of up to plus 1 volt measured to a copper sulphate cell, coincident with transit system rush hours. At this time current peaks of 3 to 4 amperes were entering one station ground, flowing through the pipe, and out at the other end.

Fig. 10. Reel of 3-conductor pipe-type 120-kv cable, showing pulling eyes and end seals

A system that would protect the pipe and, incidentally, the station grounds would require very high currents. An arrangement was sought whereby the potential required could be inserted in series between the station ground and the pipe, and at the same time have a low a-c impedance to fault currents. Such an arrangement would use the station ground bed as an anode but it was thought that the yearly loss of metal could be tolerated.

It was decided to insert 2-volt secondary cells of the automotive type in series between the pipe and the station ground beds to be kept charged by rectifiers and which would, in effect, float between the rectifier terminals supplying protective current to the pipe. Investigation showed that the cells would effectively shunt a-c fault current across the rectifier terminals and prevent undue potential rise in this event.

Experience in Service

The 2 years of operation under normal load have recorded two electrical faults on the 120-kv circuit, the second directly attributable to the first, and both line-to-ground faults. Additionally, a number of gas leaks have occurred on the circuits.

The first 8 months of operation on load were without incident, except for a gradually decreasing gas pressure, particularly on the 120-kv circuit, as indicated by the charts of daily peak loading and pressure readings; see Fig. 11. During this period some small leaks were located on loosened fittings on the ancillary equipment, and were rectified.

Continued pressure decrease in the following months demanded replenishment of nitrogen from standard cylinders, pending out-of-service availability of the circuits to investigate what appeared to be leaks of more consequence.

The first line-to-ground fault on the

120-kv circuit occurred approximately 11 months after the in-service date. The second fault occurred less than 2 hours after returning the repaired circuit to service potential and load. In the first fault the gas pressure was of the order of 125 psi, whereas the pressure on the occurrence of the second fault was 230 psi.

Location and Repair of Both Faults

On the occurrence of the first fault the pressure dropped to zero on the circuit. After immediately establishing a gas feed to the circuit to maintain a slight positive pressure, the fault resistance was burned down by passing heavy current at low voltage from the turbine generators. The fault location was indicated by linascope and oscillator, finally it was accurately located using a sensitive Murray loop bridge. The fault was located 31 feet from a joint location and 2,430 feet from the Bloor Junction terminal end. The fault was uncovered within 24 hours from the time of failure.

Externally the fault had burned a hole approximately $1^1/_4$ inches in diameter through the 0.280-inch wall of the steel pipe. Removal of approximately 2 feet of pipe revealed severe local charring of the insulation on one phase right to, and including, burnout of some of the conductor and partial charring of a second phase. The third phase was undamaged. Examination of the insulation of all three conductors immediately adjacent to the fault by "boiling out" individual tapes and application of magenta dye tests revealed no moisture present nor any ionization. Visual appearance of all paper indicated adequate compound on all tapes, and no drying out of the insulation was in evidence.

The decision was made to cut all three conductors and to remove sufficient pipe to allow making of a normal 3-conductor joint. Flanges were subsequently welded to the pipe, with the cables protected from the welding heat by packing with asbestos and foil. The joints were constructed and the sleeve welded in position without incident.

Several leaks were repaired on the circuit and the system tested at 300 psi for 7 days. A d-c test potential of 200 kv was applied without incident for 15 minutes on each phase to ground, and the circuit was restored to service.

The second electrical fault occurred without drop of pressure and was again located within the confines of the repair joint by the linascope, oscillator and Murray loop tests. On removal of the repair sleeve and on examination of the faulted phase, it was evident with little doubt that the heat of welding the flange for the first repair had damaged the cable resting on or near the bottom of the pipe. The other two cables were undamaged; also the three cables in the vicinity of the opposite flange, after very careful inspection, showed no indication of heat damage.

The repair to the faulted phase was carried out by cutting the conductor and inserting a lengthened ferrule, and taping a normal single-conductor joint. The flange and 2-foot section of attached 6-inch pipe were slid back to make room for the joint by cutting out a short section of the 6-inch pipe. This method permitted more thorough wrapping of the cables under the weld region joining the 6-inch pipe with the flange to the rest of the pipe. Alternate layers of asbestos paper and aluminum foil were wrapped many times round the cables for approximately 2 feet, and the weld performed over a standard split-backing ring. The 12-inch joint diameter sleeve from the repair joint was extended by two half sections of similar pipe welded together, and the whole assembly was finally coated and wrapped and supported on concrete pedestals. The circuit was again pressure-tested to 300 psi for 7 days, tested to 250 kv direct current for 15 minutes, and returned to service. Operation has been without further incident.

Possible Causes of First Fault

In the following are crystallized the findings of a joint co-operative investigation of the possible causes of, or conditions giving rise to, the first fault:

1. A lightning storm occurred in the area before the occurrence of the failure. A lightning stroke component counteroperating in range of the cable, recorded one lightning discharge 1 hour before the fault. Otherwise there were no system disturbances recorded within a contributable period of time.
2. A possible accident or imperfection during cable manufacture not detected by the routine tests.
3. Possible damage during shipment or installation of the particular length of cable.
4. A local hot spot due to the heterogeneous nature of the surrounding soil.

One other observed fact was the steady decrease in gas pressure throughout the 11-month period prior to the fault, as charted in Fig. 11. However, the results of test data, particularly those of Fig. 6, reference 3, and the experience and tests of others, were considered sufficient basis for allowing the pressure to drop as shown without taking the circuit out of service.

Examination, as explained previously, did not reveal any indication of heating or drying out of the insulation. Nevertheless, in an effort to obtain more data on the possibility in item 4, a number of thermocouples were attached to both pipes. Records have so far indicated no pipe temperatures exceeding 27 C. However, it has not been possible, as yet, to duplicate the circuit-loading conditions together with the soil environmental conditions which preceded the fault.

Gas Leaks

During the repairs of the electrical faults, the trifurcating joints and potheads were carefully examined and checked for gas leaks. Some potheads showed deformation of the neoprene gaskets at the top porcelain-to-cap seal, caused by uneven tightening of the cap-retaining bolts. To repair these leaks, gaskets were replaced and bolts retorqued at daily intervals.

Leaks were found at several of the cast plumbs, one on a pothead and others on the trifurcating joints. Of these, a number were rectified by recasting new metal in the original mold. Two cast plumb could not be sealed completely by this relatively simple process, and the original mold bodies were replaced with split-mold bodies of more ample dimensions.

More than 85% of the original cast plumbs are in satisfactory operation after repeated pressure tests of the system at 300 psi for long intervals during the fault repairs. This is considered, under the circumstances, reasonably satisfactory

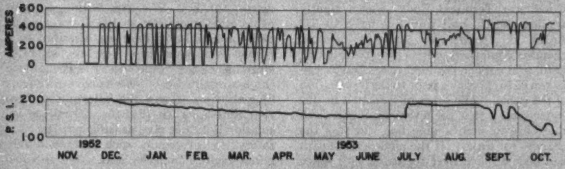

Fig. 11. Chart of peak daily load and gas-pressure 120-kv circuit

evidence of the soundness of the cast-plumb technique.

The troubles experienced and the nature of the successful remedial measures have indicated that the original molds, unless the cast is skillfully and carefully made, were of dimensions not quite sufficient to allow for all the vagaries and degrees of skill encountered in the field.

Summary

The features of this installation of pipe-type gas-pressurized cable may be briefly enumerated:

1. Seamless aluminum-sheathed terminal ends for high-voltage high-pressure operation.
2. Complementary components such as rubber-sandwich protective covering and high-pressure pipe-line insulators to permit operating aluminum-sheathed terminal ends with sheath currents interrupted.
3. Hollow-core conductor to facilitate gas feeding through high-pressure terminals, and to obtain an improvement in application of gas pressure to the dielectric.
4. High-pressure potheads without inner pressure-retaining chamber.
5. Cabling of conductors for the pipe-type cable.

The application of these features to the gas-pressurized pipe-type cable system has produced a pipe-type cable system of simple design, without encumbrances of complex accessories. It should be remarked, however, that several improvements of design details have become evident during the manufacture and installation, which when applied in future will permit further economies and refinements for more reliable field application.

◆

Discussion

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.): It is useful to note a few of the comparisons between these very interesting Canadian installations and the practice which is current in the United States. The use in the terminals of a pressure resistant porcelain shell is of interest since the customary design in the United States which uses an inner "stop tube" to substain the hydrostatic pressure was developed when a porcelain shell with assured strength was not available.

The aluminum-sheathed terminal cable sections, compared with United States practice of unsheathed cable in copper pipe is noted. The method here used to prevent circulation of current in these sheaths, while effective, seems unduly expensive compared with the simple United States practice of insulating the hardware of the terminal base from the supporting structure.

The use by the authors of flush ferrules in the splices has worked nicely with their type of conductor. The use of a flush connector (ferrule) makes it very much easier to produce a joint having a dielectric strength equal to that of the cable; conversely, a connector much larger than the conductor is reasonably acceptable only if a strength considerably less than typical of the cable is expected from the joint.

It is noted that the cable saturant used is similar to that of United States practice though of lower viscosity, yet of greater viscosity than that currently used for so-called solid-type cables. We believe that the greater viscosity used in the United States has material advantage in terms of long life than does the more fluid saturant. There are some problems occasioned by the higher viscosity but these have all been proved surmountable.

L. I. Komives (The Detroit Edison Company, Detroit, Mich.): The Detroit Edison engineers would like to congratulate the authors and their respective companies on their paper. Because of our close tie with the Ontario-Hydro System and our predilection for high-voltage, gas pressure cables, we are particularly interested in their problems.

Mention was made of the use of 4-mil bronze tape intercalated with polyethylene tape which was to serve as a moisture seal. When it was found that the bronze tape tended to open when the cores were cabled together, could it have been possible to substitute a soft copper tape for the bronze tape in the rest of the order? In Detroit we are using two tapes in our seal, first a soft and then a half-hard copper tape.

The viscosity of the impregnating compound is given as 4,000 Saybolt universal seconds (SUS) at 50 C. While the viscosity is quite a bit higher than compounds usually used, in Detroit we prefer a compound with a viscosity of about 80,000 SUS at 50 C (3,000 at 100 C and 250,000 at 100 degrees Fahrenheit). We think that the higher viscosity of the compound in such pipe-type cable at operating temperatures, the less likelihood there is of quick migration of the oil from the insulation into the pipe. Was the selection of the higher viscosity based on similar reasoning?

In connection with the discussion of leaks and gas-charging controls in Fig. 8 and gas pressure chart in Fig. 11, we wonder whether the aluminum sheath mentioned in the first paragraph of the section "Single-Conductor Terminal Ends" was a tightly applied sheath, and would it have to be? Again, in Detroit we prefer a pressure chamber comprised of steel pipe, trifurcating head, and copper terminal risers, which can be tested for pressure prior to the installation of the cable. The other observation in this connection is that the fewer gas connections there are in such a pipe line, the less the chances for leaks. If the aluminum sheath had been applied over the cable with space between the shielding tape and the aluminum sheath, one connection shown in Fig. 8 to the trifurcating joint would have been sufficient. The gas pressure in the three terminal lengths would have been equalized with the pressure in the pipe through the loose aluminum sheath. At least three valves, three pipe insulators, and six connections, plus one of the manifolds, could have been dispensed with. We cannot help but feel that there would have been less likelihood of leaks in such construction.

We noted with interest that the terminals were tested with 300-psi air pressure for 6 days and that some sustained this pressure for several weeks' duration. Could the authors enlighten us as to whether they observed any cold flow or other disturbing phenomena at the jointing surface with the porcelain and hardware during these tests?

The pipe-protective covering is described in detail and mention is made that the coating proved to be so poor that cathodic protection had to be employed to protect the pipe. In Detroit, as well as in many other places in the United States, very good results have been obtained with the use of Somastic covering for such pipe lines. Is this available in Canada, and was it considered for use on this line?

With many other cable engineers who read this interesting paper, we also wondered what caused the failure on this cable after 11 months of service? We have an experimental line in which a cable similar to the Toronto cable employing 400 mils of insulation was tried for a number of months at fairly high temperatures, operating at the rated 120 kv. We had failure on this cable after operating at 100 C for a while and the cause of failure was ascribed to a turned-over paper tape next to the outer strand-shielding tape on the conductor (high-stress region). We discovered effects of ionization around the failure, and since that time have felt that the 400 mils of insulation does not give us sufficient factor of safety to overcome such comparatively minor factory imperfections. We also feel that pressure is quite important in gas cables of this type. In a self-contained gas pressure cable the temperature of the conductor is not very different from that of the pressure container (reinforced lead sheath) and thereore the number of the nitrogen molecules in the butt space near the conductor are not reduced to such a degree as can happen in a pipe-type cable under similar conditions. The expansion of the oil in the self-contained cable being restrained by the comparatively tight sheath will also increase the gas pressure in the butt space to greater extent than in a pipe-type cable of similar construction. In view of this, the ionization voltage in the butt space near the conductor in a pipe-type cable is lower than in an equivalent self-contained cable at higher temperature. We agree that results of test data do permit the dropping of the pressure to even less than 125 psi; however, we do not do this in Detroit. We do not operate our cables normally below 205 psi. The pressure may drop to 190 psi before an alarm rings, and in an emergency we may operate the cable at much lower pressure for a short time. We feel that if we do this we are definitely impairing the life of the cable.

In Detroit we believe that the high gas pressure pipe-type cable is the simplest and most economical type of cable to install and maintain. We now have over 50 miles of this cable in service at present and we are installing several additional lines.

L. Meyerhoff (General Cable Corporation, Bayonne, N. J.): It is noted that the shield construction of the cables consisted of a 4-mil bronze tape, intercalated with a 5-mil polyethylene tape, followed by two 4-mil copper tapes intercalated with each other and a 70 × 200-mil copper skid wire. This construction did perhaps insure a good mositure barrier, as suggested by the authors but it may be noted that it also resulted in a shield of extremely low electrical resistance.

In Table IX of reference 1 of this discussion there are given measured values of the shield resistance of three different cables in which the shield constructions were similar to those described. Calculation shows that the resistance of the two intercalated 3-mil copper tapes in those three cables is, on the average, 1.55 times the calculated resistance of a copper tube of 6-mil wall thickness. Assuming that the same factor is valid for the authors' cables, it will be found that r_s', the shield resistance minus skid wires, is 240 microhms per foot for the cable with 385-mil insulation and 205 microhms per foot for the cable with 565-mil insulation at 30 C. The skid wires in parallel with the tapes make the values of r_s, the shield resistance, 225 and 195 microhms per foot respectively.

According to equation 5 of reference 2 of this discussion the incremental conductor resistance ΔR_s due to shield circulating current is

$$\Delta R_s = \frac{555}{r_s} \text{ microhms per foot}$$

and, from equation 13 of reference 1 of this discussion, the incremental conductor resistance $R\Delta_s'$, due to shield proximity effect is

$$\Delta R_s' = \frac{210}{r_s'} \text{ microhms per foot}$$

Both these equations apply for triangular configuration of the conductors and will be approximately correct for three cabled conductors.

Thus, at 30 C the incremental conductor resistances due to shield loss will be

Cable with 385-mil insulation, 2.46+0.87 = 3.33 microhms per foot.

Cable with 565-mil insulation, 2.84+1.02 = 3.86 microhms per foot.

Since the conductor resistance at 30 C is 9.6 microhms per foot, the shield loss adds 35% (in terms of d-c conductor loss) to the loss of the system in one case, and 40% in the other. These values compare with about 2.5% for the shield structure as originally contemplated by the manufacturer. At operating temperature the incremental conductor resistance due to shield loss will be 12 or 14% lower than at 30 C, but obviously this does not change the general picture.

In their discussion of the reported cable failures on their system the authors mention as a possible cause "a local hot spot due to the heterogeneous nature of the surrounding soil." It is suggested that the high losses in the shields may also have contributed materially to the overheating of the cables.

1. A-C RESISTANCE OF SEGMENTAL CABLES IN STEEL PIPE, L. Meyerhoff, G. S. Eager, Jr. *AIEE Transactions*, vol. 68, pt. II, 1949, pp. 816–34.

2. A-C RESISTANCE OF PIPE-CABLE SYSTEMS WITH SEGMENTAL CONDUCTORS, AIEE Committee Report. *AIEE Transactions*, vol. 71, pt. III, Jan. 1952, pp. 393–414.

Stephen Kozak and Colin Prescott: In Mr. Atkinson's remark regarding prevention of sheath currents at the terminal ends, it is not clear which method he considers expensive. The terminal hardware is simply isolated from the supporting structure perhaps very similarly to United States practice and is certainly not expensive. The pipeline insulator in the 3/8-inch outside diameter copper gas feed line, though operating at 200 psi, is far from expensive, and compares most favorably with United States practice of insulating the oil feed lines. The asphaltic and rubber sandwich corrosion protection on the aluminum sheath is necessary for corrosion protection. Isolation of the sheaths of course is a corollary function but similar precautions would be advisable regardless of what materials the buried riser pipes were formed.

As confirmed by Mr. Atkinson, the joint design employing flush ferrules permits easier attainment of joint electrical strength equal to that of the cable. Not only is the stress distribution more favorable, and the maximum value correspondingly reduced, but the smooth surface permits use of straight paper hand-applied tape, intrinsically superior to creped paper tape. Not only does a more compact and denser joint result but the quality of the paper and the type of impregnating compound is at the cable manufacturer's control.

Mr. Komives' searching observations arappreciated. In respect to the shielding tapes, Mr. Komives' remarks have prompted a review of the experimental data compiled in 1951, and the actual production specification cards for the cable. We must admit to an error in describing the make-up of the shields as detailed in the section "Pipe Cable: Design and Manufacture," and in Table I. The shield construction supplied was

One $1^1/_2$ × 0.005-inch polyethylene tape intercalated with one 1 × 0.004-inch commercial bronze tape.

One 1 × 0.004-inch soft-copper tape intercalated with one 1 × 0.004-inch commercial bronze tape.

Of several solutions investigated to better the behavior of the tapes during cabling operations, the rugged and conservative shield construction just described was adopted for this first installation. At the time, there was no indication of how the various shield constructions would handle in pulling the cabled lengths through the somewhat arduous pipe section pulls. Our findings during installation have shown that elaborate shielding and moisture seals are not necessary for cabled conductors since the cabling of the conductors proves attractive in ease of handling, pulling, and wear on skid wires and shielding tapes. Our next design would consider either Mr. Komives' construction or possibly only one semihard copper tape intercalated with polyethylene tape.

The impregnating compound was selected after many tests of its qualities, both electrical and mechanical, and several factors influenced the choice of viscosity. Primarily the viscosity of 4,000 SUS, though not as high as that preferred by Mr. Komives, was considered more than sufficiently high to prevent migration of any consequence. The hollow-core design of gas-pressurized cable with the gas permeating outwards from the core presents a cable structure not as susceptible to leaking out of the compound as does the design of cable employing the "segmental" conductor. Such concepts as consideration of the compound in suspension in the gas, the balance of pressures in the insulant structures, the surface tensions between the tapes and the compound density, and the impregnation procedure must all be assessed along with considerations of viscosity. The compound selected was the best of several studied taking all factors into account. The compound has extremely low and stable power factor, and a high dielectric strength. It is outstanding in its nonadsorption of moisture characteristic. Another factor influencing the choice of compound was its suitability of handling in the existing cable plant, in respect to the hollow-core principle; a very viscous compound would be practically impossible to blow out of the core. Yet another factor was the desire to avoid the disadvantages of lifting the cable out of the impregnating tanks prematurely. Our strong preference is toward full completion of the impregnating process under applied pressure during the cooling cycle down to room temperature.

We agree with Mr. Komives that the gas-charging panel can be simplified. Our present thinking would point to halving the number of manifolds and valves, but not for the reasons put forth by Mr. Komives. We would maintain a tight aluminum-sheathed cable and a separate feed to each pothead, if only for the reason that a pothead can be replaced or repaired without losing any of the gas in the pipe. Since nitrogen in Canada is expensive, the feature is worth while. The aluminum-sheathed terminal lengths are likewise pressure-tested before installation, are very easily handled without need of threading exposed cable through long risers, and the seals to the pipe and to the pothead are simply made. The pothead oil is contained adequately by a silk-tape poultice over the sheath, potheads can be installed at whatever time is suitable, and no welding or specialties are required. In other words, the procedure for installing terminal ends on high-pressure cable is kept almost as simple as terminating ordinary solid-type high-voltage cable.

With respect to pressure tests on pothead assemblies and the behavior of gasket surfaces, one disadvantage noted was the necessity of torquing the bolts of the gasketted joints several times in the field before applying gas pressure to the pothead. Normally these gasketted joints are fully torqued in the factory, but in this case the components had to be separated and then reassembled in the field because the pothead metal parts adaptable to our stress cone diameter could not be obtained in time. The gaskets are confined in recesses in the metal parts, and once the initial compression and set have been realized by torquing, no gasket displacement, bulging, or distortion was evident even after the severe pressure test cycles.

Unfortunately Somastic coating for the pipes could be supplied only by shipping the pipe to the United States for coating. The expense and the delay would have been prohibitive and the likelihood of damage during shipment increased. However, the coating specified would, we feel, be entirely adequate were proper quality control and determined inspection stringently observed.

Some of Mr. Meyerhoff's observations can be answered by referring to our reply to Mr. Komives, wherein we corrected our reporting of the shield assembly construction. We are not in agreement with the factor of 1.55 quoted; indeed the factor varies quite appreciably with the extent of overlay or overlap in the intercalation practice. Our test measurements of the resistance of shield assemblies consisting of two intercalated copper tapes with 75% overlay showed that the factor was 2.06 for dry tapes, and for the same construction with the tapes applied with a film of viscous cable compound, the factor was as high as 5.56. Applying the more pessimistic dry value to an effective calculated resistance of a thin-walled copper and bronze tube of 0.006-inch thickness (assuming conductivity of the bronze is 50%), the incremental conductor resistances due to shield loss are as in Table II.

Table II. Incremental Conductor Resistances

Cable	$\Delta R_s+\Delta R_s'$	R_{ac}/R_{dc}*	R_{ac}/R_{dc}†
120 kv (0.385-inch paper)	1.48+0.493=1.97	1.19	1.08
161 kv (0.565-inch paper)	1.642+0.577=2.22	1.22	1.07

* Ratio at the shield for 1×0.004-inch copper tape and 2×0.004-inch bronze tape assembly at operating temperature.

† Ratio at the shield for the formerly contemplated shield assembly of two 0.004-inch bronze tapes each intercalated with polyethylene tape.

The shield losses are therefore much less than Mr. Meyerhoff's 35% and certainly these losses do not reduce the rating as severely as Mr. Meyerhoff would imply.

The change in shielding construction after running the experimental length was not enacted without due consideration of the slight increase in losses, but with the knowledge that the conservative assumptions made in the original calculations for conductor size would permit an additional copper tape without significant reduction in rating.

Epoxy Resin Casting of Dry-Type Current Transformers

W. C. FARNETH
ASSOCIATE MEMBER AIEE

GEORGE GALLOUSIS
ASSOCIATE MEMBER AIEE

Synopsis: The use of synthetic resins and casting techniques for the embedment of electrical components is continually increasing in the United States and in Europe. This paper presents to the industry some results of approximately 3 years of work with epoxy resins and casting techniques at Allis-Chalmers Manufacturing Company.

Although the work to date has been confined primarily to a 600-volt insulation-class indoor-outdoor, dry, window type of current transformer, experience clearly indicates that the extension of the use of these techniques and materials to a higher voltage class and larger dry-type current transformer applications is not only desirable but feasible.

EPOXY resins[1] inherently possess characteristics which make them suitable for use as insulation for dry-type current transformers. These characteristics include good adhesion to metal and ceramics, good mechanical strength, good dielectric properties, good resistance to temperature variations, low moisture absorption, low shrinkage during cure, and high resistance to solvents. In addition, the epoxy resins are well suited to use in casting processes which are relatively simple and inexpensive.

Experimental castings of units of higher voltage class have been made. These units, all presenting more difficult configurations, are now being evaluated. Prototypes of such units are shown in Fig. 1. The more complex configurations of current transformers require careful design to resolve coil support and shrinkage problems as well as to keep the total amount of resin used to an economical minimum. The designer, however, has many types of epoxy resins available to him. Proper adjustment of the base resin formulation, the resin-filler proportions, and the casting process make successful new applications possible.

For the specific application of the current transformer shown in Fig. 2 the use of the epoxy resin eliminates the need for a conventional case and bushing and consequent sealing and gasketing problems. (A noncast conventional unit is shown in Fig. 3.) The epoxy resin casting technique results in a rugged unit which may be used for either indoor or outdoor applications.

The four manufactured current rat-

---

Paper 55-34, recommended by the AIEE Transformers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing November 16, 1954.

W. C. Farneth and George Gallousis are with the Allis-Chalmers Manufacturing Company, Pittsburgh, Pa.

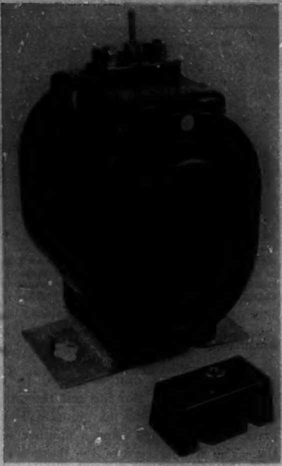

Fig. 2. Allis-Chalmers Manufacturing Company type-TWM 600-volt class cast current transformer

ings (200, 5-ampere; 400, 5-ampere; 600, 5-ampere; and 700, 5-ampere) are all satisfactory for use at 200-per-cent (%) continuous rated primary current. A typical 400-ampere unit element is shown in Fig. 4. It consists of an electric steel core insulated by means of pads and creped Kraft paper tape upon which the secondary winding is placed. Secondary terminals and a base-mounting arrangement complete the element assembly.

Casting

Smooth, inexpensive metal molds coated with release agents are used in the casting process. Each mold is provided with a bracket supporting the transformer element, an arrangement for positioning and aligning the secondary terminals, a pouring reservoir, and a clamping arrangement. The initial casting steps include the drying of the transformer and the establishment of a uniform mold and element temperature. To achieve this the transformer is inserted in the mold and the combination placed in an air-circulating oven.

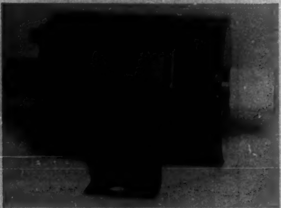

Fig. 3. Conventional outdoor window-type current transformer

The epoxy base resin to which a filler has been added is heated to the same temperature as the transformer and the mold. This step is followed by the introduction of the hardener or catalyst into the resin, the thorough stirring of the resin-hardener mixture, the careful filling of the molds, and the curing of the resin in an air-circulating oven. Upon removal from the mold the transformer is cooled to room temperature, the flash is removed, and a rating plate, customer's number plate, secondary terminal board, and base are attached.

The material evaluation tests[1] which have been performed to date are of two types, those performed on actual transformers and those performed on material samples. The tests on transformers are discussed first.

Long-Time Tests

Of primary importance in evaluation are long-time tests under actual operating conditions. On the roof of Allis-Chalmers' Pittsburgh Works, since October 1952, prototypes of the present units have been operating continuously at 200% rated current. Approximately every 3 months, measurements of capacitance, dissipation factor, insulation resistance, and resin hardness are made and recorded. These measurements indicate no significant change in the condition of the units. Values recorded on a representative 200, 5-ampere unit appear in Table I.

The primary conductor for these tests consisted of a steel bar 9 inches long fitted tightly into the primary opening of the transformer.

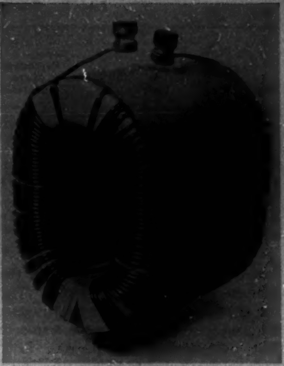

Fig. 4. Element of 400, 5-ampere type TWM

Thermal Cycling

Additional transformers underwent thermal-cycling tests for 1,008 hours. The temperature sequence of each cycle was −30 degrees centigrade (C), +75 C, and room temperature. During the tests units progressed directly from one cycle to the next, remaining in each temperature condition for 24 hours. No voltage or current was applied to the transformers during these tests. Again, as in the case of the long time tests, capacitance, dissipation factor, insulation resistance, and resin hardness were measured. The test results in Table II indicate no significant change in these characteristics. These transformers withstood a standard 2,500-volt 60-cycle one-minute applied potential test from secondary to ground after 2-cycles, and again after 14 cycles.

Thermal Aging

Thermal aging tests were also performed during which units were subjected to a temperature of 130 C for 1,500 hours. The standard 60-cycle applied potential test of 2,500 volts for 1 minute was applied after 500 hours and 1,000 hours, and was successfully withstood by each unit.

The test results presented in Table III

Table I. Representative 200, 5-Ampere Unit Long-Time Test Results

	October 1952	September 1954
Primary to secondary and ground		
Capacitance, micromicrofarads	82	54
Dissipation factor, %	0.8	1.1
Secondary to primary and ground

F	325	0.5	92

Resistance measurements, made at the same time as the capacitance and dissipation factor measurements, were equal to or greater than 10^6 megohms throughout the test.

indicate no appreciable change in the characteristics of the units tested. The test at 130 C for 1,500 hours was based on the average copper rise of a 600, 5-ampere unit operating at 200-per-cent load. This rise was found to be less than 30 C. Therefore the average copper temperature of a unit operating continuously at 200-per-cent load in a 30-C ambient would be less than 60 C. Assuming a 10-degree rule of insulation life (the insulation life is halved for each 10 C increase in temperature) 1,500 hours at 130 C is approximately equivalent to 20 years at 60 C.

Artificial Weathering

Transformers were operated for 1,000 hours at 200-per-cent rated current in the artificial weathering chamber shown in Fig. 5, built expressly for this test. The chamber used was a tank above which a bank of ultraviolet lamps were positioned. The intensity of the lamps was controlled to provide an ultraviolet intensity of approximately five times the maximum intensity of the sun and an infrared intensity equal to the maximum intensity of the sun. Fresh tap water was automatically sprayed on the units for 10 minutes every hour. This test indicated no appreciable change in capacitance, dissipation factor, secondary resistance to ground, or resin hardness.

Weight Loss

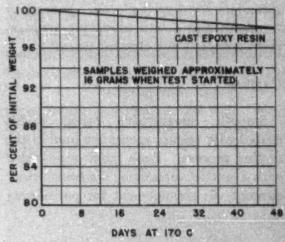
Several material tests were made. The first, a good indicator of the thermal stability of material, was a test of weight loss versus time at elevated temperature. Fig. 6 shows that the weight loss after 46 days of aging in an air-circulating oven at 170 C was only 1.8 per cent for the specific resin tested.

Dielectric Strength Versus Temperature

Tests of dielectric strength versus temperature were also made on sheet sample castings of the material. These tests, performed on 80-mil-thick 6-inch square samples, in accordance with American Society for Testing Materials Standards,[2] were 60-cycle 1-minute step-by-step hold tests using standard 2-inch diameter electrodes. Creep occurred around the edge of the samples at room temperature and at 50 C in air. These tests were therefore made under oil. The other test points at elevated temperatures were obtained in an oven in air. Test results are plotted in Fig. 7. A comparison has been made on this curve between the epoxy resin tested and asphalt impregnated paper. The data indicate the resin to be superior to the asphalt-impregnated paper.

Flammability

Fig. 8 shows a unit subjected to a flammability test. For this test the unit was exposed to an oxygen-acetylene flame for 30 seconds using a number 46 tip. The temperature of the flame was approximately 3,500 C. On removal of the flame the resin continued to burn slowly for 8 seconds after which it extinguished itself. Very little smoke was evolved during this period of burning and no irritating effects were noticed. After cleaning the charred resin from the area to which the flame had been directly applied, it was found that the charring had occurred to a depth of 3/16 inch. Beyond this depth the resin was apparently still solid.



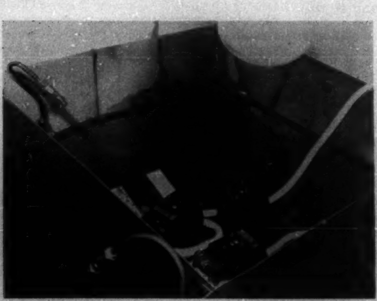


Fig. 5 (left). Units in artificial weathering chamber

Fig. 6 (upper right). Weight loss versus time at elevated temperature

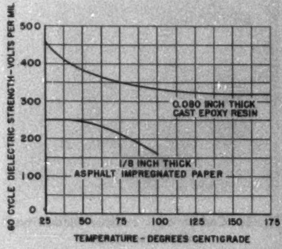

Fig. 7 (right). Dielectric strength versus temperature

Fig. 8. Application of 3,500 C oxyacetylene flame to type TWM

A number or the units were placed in an incinerator at 425 C. No unusual behavior was observed during these operations. On removal from the incinerator the physical dimensions of the units were found to be unchanged, but the charred resin was easily chipped off. From the described tests it is apparent that the operation of these units under conditions of extreme heat is satisfactory and also that the units do not constitute a fire hazard.

Quality Control

Prior to shipment, each production unit is subjected to an unusual quality control insulation test. Each unit is immersed in a saline solution to a depth slightly below the secondary terminals. The salt solution is grounded, thereby grounding the mounting feet and core and simultaneously acting as a primary conductor. A 60-cycle test voltage of 4,000 volts is then applied to the secondary terminals for 1 minute, stressing the resin from secondary to primary and ground. This test voltage, which is in excess of the 2,500-volt 60-cycle dielectric test between secondary and ground as specified by American Standards Association standards,[3] results in maximum information from a single testing operation. It checks the condition of all the resin between the secondary and the saline solution.

Summary

The use of synthetic resin and casting techniques for the embedment of electrical components is continually increasing. The use of such techniques and an epoxy casting resin has produced successful 600-volt insulation class window-type current transformers which are now in large-scale production. Material and transformer evaluation tests made to date indicate that the production of higher voltage class and larger current transformers is feasible. Several prototypes of these more complex units have been experimentally produced.

◆

Discussion

Dr. A. A. Halacsy (I-T-E Circuit Breaker Company, Philadelphia, Pa.): The authors mention that their tests indicate the feasibility of the production of higher voltage class and larger current transformers. I should like to mention some past development of such current transformers.

The idea of producing such a 15-kv class wound-type current transformer, fully encapsulated, was considered in 1949. Tests were carried out and prototypes produced in 1952 and 1953 in the factory of Eastern Power Devices, Toronto, the I-T-E Circuit Breaker Company's plant in Canada.

A prototype of a 15-kv class 300/5-ampere current transformer, having a 5-turn primary and a wound-steel core, showed a remarkable reduction in the length of a current transformer, with taped insulation from about 23 to 11 inches. This was achieved by increasing the creepage with the use of cast ribs, which would not be possible in the case of taped insulation.

Today our company is producing quite a few 15-kv epoxy resin encapsulated devices, and we can be sure that epoxy casting will be used for considerably higher voltages in the not too distant future.

Paul Wildi (Pacific Oerlikon Company, Tacoma, Wash.) and **A. Ernst** (Oerlikon

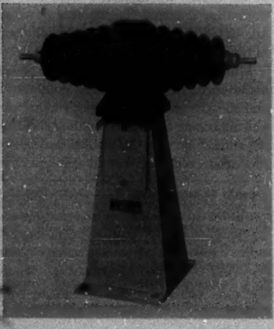

Fig. 9 (left). Line of epoxy-cast indoor current transformers for 10-kv rated voltage, with single and double secondaries

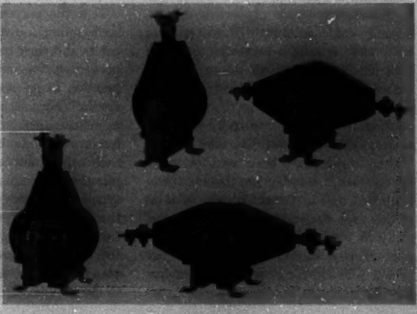

Fig. 10 (right). Current transformer for outdoor application. Rated voltage 16 kv

Engineering Company, Zurich, Switzerland): The use of epoxy resin as an insulator for dry-type current transformers is definitely an improvement over previously employed techniques. Its application is, however, not limited to low-voltage instrument transformers. The low-dissipation factor, the high dielectric strength and, when used with proper fillers, the good heat-transfer characteristics of the material, make it ideally suited for high-voltage applications. Our company adopted this technique in 1948 and is currently building epoxy cast instrument transformers up to a rated voltage of 60 kv.

Fig. 9 shows a line of indoor current transformers as built at present for 10-kv rated voltage, 16-kv maximum operating voltage, and 42-kv low-frequency one-minute withstand voltage. The design offers considerable advantage over the conventional design, specifically, high resistance to moisture, very high instantaneous current rating (300 to 500 times rated current), economy in manufacturing, and very little tendency to accumulate dust and dirt. The excellent weather resistance of the insulation material offers the possibility of using cast resin application for outdoor use.

Fig. 10 shows a current transformer with a completely embedded secondary core for use on electrical traction systems. Current transformers of this type have been in use for longer than 5 years. The one shown is rated 16 kv, 500/5 amperes, at $16^{2}/_{3}$ cycles per second.

Field experience with this new design of current transformers indicates that we have not yet reached the limit of performance of the new material. We are at present experimenting with prototypes up to a rated voltage of 380 kv.

W. C. Farneth and George Gallousis: We appreciate the discussers' comments. We are aware, of course, that other higher voltage work with epoxy resins has been in progress. This has been indicated in our references and synopsis. However, in higher voltage class applications, a conservative approach demands that transformers utilizing a new material and process be subjected not only to routine insulation tests but also to accelerated and long-time tests comparable in severity to those outlined in our paper. Results of such tests or results of field experience are a valuable addition to the information now available in this field.

Mineral-Insulated Metallic-Sheathed Cables

C. A. JORDAN
MEMBER AIEE

G. S. EAGER, JR.
ASSOCIATE MEMBER AIEE

CERTAIN inorganic materials of mineral or mineral-like nature have long been recognized as possessing properties which make them attractive for use as insulation for electric cables. Materials that have received consideration as insulants are magnesium oxide, aluminum oxide, kaolin, asbestos, powdered glass, and zircon porcelain, to mention a few. Of these, magnesium oxide is the only material (aside from low-density fibrous asbestos) that has received important practical application to date. The principal factors that have influenced this status are: 1. magnesium oxide, in proper form, makes an excellent cable insulation, and 2. it has the characteristics needed for practical cable fabrication, and field handling and installation.

The nature and properties of inorganic cable insulants in general are such as to require a protective covering over all. In the case of the cables here described, this takes the form of an impervious metallic sheath.

Mineral-insulated metallic-sheathed cables, although relatively new in the United States, have been used for many years abroad, notably on the European continent and in Great Britain. Cables of this type were first produced commercially in France in 1934. In 1937, production was started in Great Britain. World War II temporarily retarded further development in other countries, particularly in view of the relatively complex and expensive plant required for manufacture. In 1946, however, the company with which the authors are associated first produced prototype mineral-insulated high-frequency coaxial cables for military use (since standardized as the *RG-81/U* and *RG-82/U* cables of Joint Army-Navy Specification *JAN-C-17A*[1]). In 1949, this company made available in the United States 600-volt rated single-conductor and multiconductor mineral-insulated metallic-sheathed power cables, and fittings therefor. In all three countries the cable materials and constructions and the methods of fabrication, have been substantially similar; in particular, magnesium oxide has been the basic insulant employed.

It is the purpose of this paper to describe mineral-insulated metallic-sheathed cables and their terminating fittings with particular reference to United States practice, to present the principal properties and characteristics of such cables, and to indicate some of the novel and unique features and characteristics which make such cables advantageous for many applications. In this country, cables of the type under consideration are offered under the trade name Pyrotenax Safety Mineral Insulated Wiring, and have been given the generic designation by the industry as a whole (see the National Electrical Code) of type *MI*. The latter designation will be used in the following for the sake of convenience and brevity.

Cable Materials, Constructions, Sizes, and General Dimensions

MATERIALS

While a number of choices of conductor and sheath materials are theoretically possible, performance, economics, and manufacturing considerations nominate copper as the metal of principal usefulness for mineral-insulated power cables. Its electrical properties are unexcelled in practical conductor metals, and it possesses in high degree the strength and ductility essential for fabrication of this type of cable in commercially long lengths. (This will be clearer from the discussion of manufacturing methods to follow.) For these reasons, present standard type-*MI* power cables consist essentially of one or more solid copper conductors embedded in finely divided, highly compressed magnesium oxide insulation, the whole enclosed in a continuous, seamless copper sheath. Conductors and sheaths of all cables are annealed dead-soft to normalize internal mechanical stresses and to facilitate handling and installation in the field.

Mineral-insulated cables have been made abroad with aluminum conductors and sheaths, and with copper conductors and aluminum or aluminum alloy sheaths. All-aluminum type-*MI* cables have been produced experimentally in this country.

Paper 55-54, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 19, 1954; made available for printing December 2, 1954.

C. A. JORDAN is with the General Cable Corporation, Perth Amboy, N. J., and G. S. EAGER, JR. is with the General Cable Corporation, Bayonne, N. J.

Table I. 600-Volt Type-MI Power Cables, Standard Constructions and Sizes

No. of Conductors	Size Range, AWG Inclusive
1	16 to 4/0
2	16 to 4
3	16 to 4
4	16 to 6
7	16 to 10

In addition to the standard copper *MI* power cables, there is in regular production here at present a special small cable which has conductors of a copper-nickel resistance alloy and a sheath of copper, designed for heating service. The British regularly produce thermocouples of the *MI* type having chromel-alumel and copper-constantan couple conductors and sheaths of nickel-chrome and mild steel. They also produce standard type-*MI* thermocouple compensating cables having these same conductor combinations and iron-constantan, as well, and sheaths of cupro-nickel and mild steel. These various thermocouple cables are available in two basic diameters, 0.266-inch and 0.125-inch respectively. Aside from these cable applications, magnesium oxide insulation is used in heating elements, such as Calrod units.

Sizes and Constructions

Type-*MI* 600-volt power cables are available in single-, 2-, 3-, 4- and 7-conductor constructions, as may be required for particular applications. The standard size ranges for the various constructions are indicated in Table I.

The special 2-conductor heating cable just referred to has 0.038-inch diameter copper-nickel resistance alloy conductors, compressed magnesium oxide insulation, copper sheath over all. It has an over-all diameter of 0.246 inch, and is rated 300-volt.

As will be evident from the manufacturing methods to be described, the conductors of type-*MI* cables are not directly die-drawn. As an unavoidably inherent characteristic of this type of cable, therefore, the conductors cannot be expected to meet the exactingly high standards applicable to die-drawn wires with respect to surface finish and close diameter tolerance. This, however, involves no practical disadvantages or sacrifice in the use of such cables. Conductor size is conveniently and closely controlled by resistance measurement in lieu of conventional diameter measurement by micrometer. Conductor concentricity and uniformity of cross-sectional area are completely adequate for all practical requirements. The sheath of type-*MI* cables, being directly die-drawn, can be and is held to close diameter tolerances to ensure good match with the appurtenant terminating fittings.

Insulation Thickness

By design in multiconductor type-*MI* power cables, the separation between surfaces of adjacent conductors (thickness of insulation) is identical to that between surfaces of outer conductors and sheath. Actually, of course, multiconductor *MI* cable may be regarded most accurately as belted cable having nominal conductor and belt insulations of the same thickness, each equal to one-half of the separation between conductors or between conductors and sheath. For simplicity and clarity, however, the term "insulation thickness" will be employed to designate the combined thicknesses of insulation and belt, i.e., the separation between surfaces of metal components. Thus interpreted, the design insulation thickness of multiconductor *MI* cables is nominally the same as that of single-conductor cables.

The thickness of insulation in 600-volt rated type-*MI* power cables varies somewhat with conductor size, ranging in approximately linear relationship (with respect to cable diameter) from about 0.060 inch for the smallest size (16 American Wire Gauge (AWG)) to about 0.080 inch for the largest standard size (4/0 AWG). Strict theoretical relationships are, however, slightly modified in some instances to gain the important practical advantage of a reduction in the required number of fitting sizes (by equalizing and grouping cables of different constructions but nearly equal outside diameters) if that can be done without violating fundamental design requirements. The nominal insulation thickness of the special 300-volt heating cable is 0.043 inch. As will be seen later, magnesium oxide insulation has such properties that in each instance the design insulation thickness is adequate for the assigned voltage rating.

Sheath Dimensions

Sheath thicknesses of type-*MI* cables are determined by both mechanical and electrical requirements, i.e., the sheath must be both feasible of manufacture and rugged enough to afford requisite mechanical protection, and must also have sufficient conductance to insure proper grounding and handling of fault currents. In the case of 600-volt *MI* power cables, sheath thicknesses vary linearly with cable diameter from a nominal value of 0.023 inch for the smallest cable to 0.039 inch for the largest. A more significant picture of electrical relations will, perhaps, be afforded by Table II, which indicates the nominal area or conductance ratio of sheath to conductor for the *maximum* size of cable of each construction. The sheath area ratios, or relative sheath conductances, of smaller sizes of cable are greater than those indicated in Table II in all instances, i.e., Table II shows the *minimum* relative sheath conductances.

Table II. 600-Volt Type-MI Power Cables, Minimum Relative Areas of Outer Sheaths

No. of Conductors in Cable	Ratio of Sheath Area to Area of One Conductor
1	0.478
2	2.35
3	2.58
4	3.74
7	8.11

For single-conductor cables, sheath and conductor area equalize at 4 AWG; for that size the ratio of sheath area to conductor area is 1.02.

As will be noted from Table II, mechanical considerations dictate sheath cross-sectional areas larger than are electrically required (in terms of an arbitrary 100 per cent (%) of the conductance of a single conductor) for all multiconductor cables, and for all sizes of single-conductor cables 4 AWG and smaller. Even in the case of the larger sizes of single-conductor cables, a single-phase circuit would have a minimum combined sheath area of about 96%, and a 3-phase circuit about 143%. These relative conductances, of course, far exceed the requirements of the National Electrical Code for grounding conductors.

General

Finally, type-*MI* cables of all sizes and constructions are very compact and relatively light, which contributes greatly to ease of handling and installation.

Methods of Manufacture

With the briefly outlined history and current status of type-*MI* cables, and their salient features and dimensions in mind, it is of interest to give some consideration to manufacturing methods, not so much with the purpose of covering tedious technical detail but rather to give users a clearer appreciation of what, aside from the inherent properties of the component materials, makes type-*MI* cables what they are.

There are two variants of the general method of manufacture. Both develop from what may, for lack of a better term, be called the "starting assembly." In so far as metal parts are concerned, the starting assembly consists of a relatively large, seamless, cylindrical copper tube and one

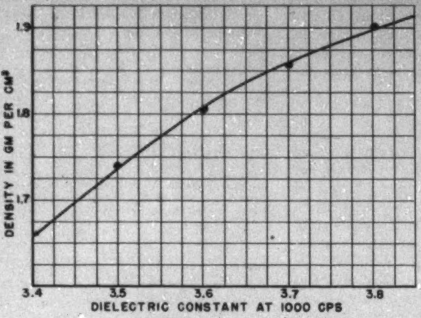

Fig. 1. Influence of density on dielectric constant

or more relatively large solid copper starting conductors, all having the same relative proportions as they will have in the finished cable.

In the older of the two methods of manufacture, magnesium oxide powder, after preliminary treatment to secure the proper condition and properties, is molded under heavy pressure into cylindrical pellets, each of which is longitudinally cored for the desired number of conductors in the cable. These pellets have, with practical clearance fits, outside diameters to fit closely into the starting tube, and core hole diameters to fit closely the starting conductors, automatically giving them the correct relative proportions for the finished cable. After complete dehydration and while still hot, the pellets, together with the starting conductors, are assembled within the starting tube, with the magnesia pellets closely stacked end to end and with the starting conductor(s) inside their core holes. It will be seen that this process affords a high degree of accuracy and uniformity of conductor spacing and insulation thickness.

In the newer of the two variants of the general method of manufacture, now coming into use because of the increased production rate it makes possible, the starting conductor(s) is placed within the starting tube, and are automatically jigged to exact position by new complex equipment which at the same time continuously and progressively feeds pretreated, dehydrated magnesium oxide powder into the tube and around the conductors, and tamps it into the correct uniform body and density from one end of the starting tube to the other. This alternate method of preparing starting assemblies also results in high accuracy and uniformity of conductor positioning and insulation thickness.

Subsequent manufacturing operations are the same regardless of the method of preparing the starting assembly. The latter is drawn down in successive stages, with the necessary intermediate anneals, to the finished size of cable in exactly the same manner as is employed in conventional wire drawing, except of course for the differences of degree occasioned by the relatively large starting size. In these drawing operations, the tube or sheath is, of course, the only component that is directly die-drawn, but fortunately it happens that the properties of dense magnesium oxide and copper, at least, are such that insulation and conductors, as well as sheath, all draw down smoothly, uniformly, and in proper relative proportions to the final cable size. The final operation after coiling the finished cable is a deep anneal to normalize internal stresses and insure proper and uniform handling properties.

This brief recital of basic manufacturing methods immediately makes it possible to understand a number of salient factors about type-*MI* cables. First, the tooling is complex and expensive, and involves a considerable time element, which makes it difficult to produce special constructions, or cables with other component materials which may or may not, when associated with magnesium oxide insulation, draw down satisfactorily in commercial coil lengths. Second, the method of manufacture lends itself only to production of solid conductors (at least there would be no practical advantage to be gained by indirectly drawing stranded conductors) and the indirectly drawn conductors characteristically differ in appearance and tolerance range from directly drawn wires, as has already been mentioned; such conductors are not necessarily inferior but merely different and in any case are completely adequate for their intended use. Finally, it is obvious that feasible continuous coil lengths of completed cables are controlled by the mass of the starting assembly and, since the starting assemblies of all *MI* cables have somewhat similar mass, feasible coil lengths of large cables are less than those of small cables. Shipping lengths are, however, commercial in all sizes and constructions, and in those comparatively rare cases where cable runs exceed available lengths the cables can readily be spliced in boxes with standard fittings.

As a natural result of the method of manufacture, which involves tremendous pressures during the drawing operations, the originally relatively dense, dry magnesium oxide insulation becomes so highly compacted that, although essentially a powder at all stages, it eventually assumes many of the characteristics of a solid. For all practical purposes of cable handling it acts as a solid, i.e., while the insulation can readily be removed from the conductors for making connections and terminations, there is little if any tendency for it to flow or chalk out when cable ends are cut and the cable is being handled and trained to position. The seemingly solid nature of the insulation also contributes much to the desirable rigid, yet flexible, handling properties of *MI* cables, and explains in considerable degree the remarkable physical properties and resistance to abuse which are inherent in this cable type.

Properties of Magnesium Oxide Insulation

Commercial magnesium oxide is obtained by calcining the natural magnesite (magnesium carbonate) or by calcining a synthetic material (magnesium-carbonate or magnesium-hydrate) produced from sea water. The electrical properties of magnesium oxide depend a great deal on the source of the magnesite, the method and degree of calcination, and the type and amount of impurities present. Experience has indicated that one of the most suitable sources of magnesium oxide for electric wires and cables is the natural calcined India magnesium oxide. Typical chemical composition of this natural magnesium oxide as used in cables is:

Magnesium oxide,	89.47%
Calcium oxide,	1.29%
Silicon dioxide,	3.88%
Ferrous oxide,	0.07%
Aluminum oxide,	0.24%
Free moisture,	0.57%*
Volatile matter (combined water and carbon dioxide)	4.48%*
	100.00%

*Expelled upon drying in normal course of manufacture.

The electrical and physical properties

of magnesium oxide depend a great deal upon the degree to which the powder is compressed. Gemant and Glassow[2] have reported that the a-c dielectric strength of compressed magnesium oxide increases appreciably as the density of the compressed powder increases.

The dielectric constant of magnesium oxide also varies with the density of the compressed powder. The magnesium oxide insulation in cables has a density in the range of 1.6 to 2.0 grams per cubic centimeter. Fig. 1 shows the variation of the dielectric constant of magnesium oxide as the density is increased. These data were taken on coaxial cables, at a frequency of 1,000 cycles per second (cps) at room temperature.

Magnesium oxide has relatively high thermal conductivity. This is advantageous for an insulation used for electric cables. The thermal conductivity is three to five times greater than that of most organic insulations used on electric wires and cables. As may be expected, the heat conductivity increases as the specific gravity (density) of the compressed powder increases.

Magnesium oxide is hygroscopic. When combined with water it forms magnesium hydroxide. The presence of free moisture quickly reduces the dielectric strength and allows an appreciable leakage current to flow. When used as an insulation in cables, arrangements must be made to prevent moisture from coming into contact with the insulation. This is accomplished by end seals which are discussed later.

Properties of Type-MI Cables

INSULATION RESISTANCE

The insulation resistance of mineral insulated cables is relatively high compared to that of most organic insulations. At room temperature it exceeds that of any extruded insulation commonly employed on cables except polyethylene. The insulation resistance decreases with increasing temperature. Fig. 2 shows typical data for single-conductor 4/0 AWG type-*MI* cable. The insulation resistance was measured at 500 volts direct current between the conductor and the sheath after a 1-minute electrification time, in accordance with the procedure of the American Society for Testing Materials (ASTM).[3] Samples were placed in an air oven for 16 hours at 120 degrees centigrade (C) for drying unprotected cable ends prior to testing, as was done prior to taking all electrical data reported in this paper.

That the data in the foregoing may be compared with those for other well-known inorganic insulations, the curve of Fig. 2 is replotted in Fig. 3. The data for alumina porcelain, muscovite mica, and high tension porcelain were reported by Lindsay and Berberich[4] and are shown in Fig. 3 for comparison purposes. The abscissas of Fig. 3 show temperature, but the values are plotted on the basis of the reciprocal absolute temperature scale, as is done in several subsequent curves in this paper. Magnesium oxide has a considerably higher resistivity than high-tension porcelain at the higher temperatures, and compares favorably with alumina porcelains. As would be expected, magnesium oxide exhibits the same general type of resistivity-temperature characteristic as the inorganic insulations reported by Lindsay and Berberich. The transition point of magnesium oxide appears to be at approximately 250 C.

POWER FACTOR

The power factor (pf) of magnesium oxide is very low compared to that of most insulations used in electrical wires and cables. The room temperature value for typical cable is generally 0.1% when measured at 60 cps, 40 volts per mil.

Typical pf data are given in Fig. 4. Measurements were made at 1,000 cps using a General Radio bridge *716A*. As will be seen later the pf of magnesium oxide insulation is substantially independent of frequency. Samples were placed in an air oven for these tests to attain the correct temperature. The samples were 5 feet long, equipped with suitable guard circuits. The pf is less than 1% up to 250 C, above which the increase is more rapid. This temperature corresponds to that observed as the transition temperature in Fig. 3.

DIELECTRIC CONSTANT

The dielectric constant of magnesium oxide insulation in type-*MI* cables is shown in Fig. 5. This value varies somewhat, as discussed previously, with the degree of compression of the powder, i.e., with its density. The dielectric constant is relatively constant for temperatures up to about 300 C, above which it increases more rapidly. These data were taken at a frequency of 1,000 cps, using a General Radio bridge *716A*. There is no sharp transition point at 250 C as observed in the case of pf and insulation resistance.

The dielectric constant is independent of frequency over the range from 60 cycles

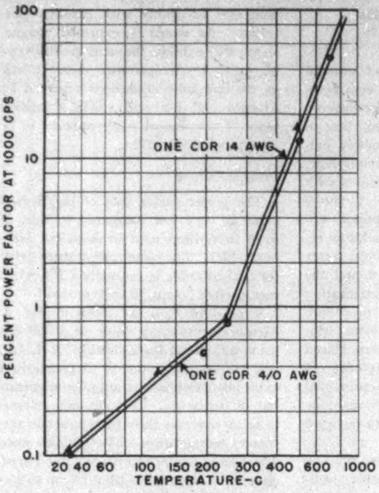

Fig. 4. Pf, temperature relation for typical MI cable

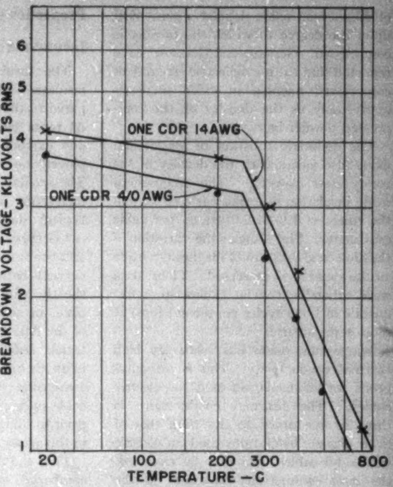

Fig. 6. A-c dielectric strength of MI cables as influenced by temperature

per second to 400 megacycles per second. This particular feature plus the low pf mentioned previously makes this insulation attractive for use in high-frequency cables, as will be discussed later.

A-C Dielectric Strength

The 60-cycle dielectric strength of magnesium oxide in type-*MI* cables is approximately 60 volts per mil when measured at room temperature, which is relatively low compared to most other insulations used on wires and cables. The breakdown voltage of typical completed cables is generally 3,500 to 5,000 volts, which is considered adequate for cable having a 600-volt rating. Performance of cable in service bears this out.

The dielectric strength of *MI* cable decreases with an increase in temperature, and at about 250 C this rate of decrease becomes greater. Typical data are shown in Fig. 6. These tests were conducted on typical *MI* cables, following generally the ASTM D 149–44 procedure.[5] Tests on 1-foot lengths were made at temperatures from 25 to 200 C in an air oven at the test temperature Tests at temperatures from 200 to 850 C were made in 5-foot lengths of cable heated by conductor current and lagged with asbestos insulation. Temperatures were measured by thermocouples strapped to the sheath which would give temperatures slightly below the insulation temperatures. An initial voltage of 40 volts per mil at 60 cps was maintained for 5 minutes, then increased 20% each 5 minutes thereafter until breakdown. The transition point is fairly close to the transition temperature (250 C) observed for the insulation resistance and the pf.

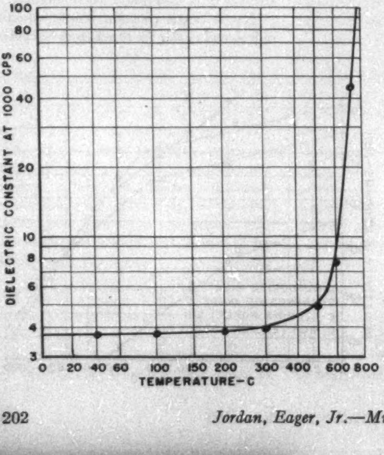

Fig. 5. Dielectric constant of MI cables, effect of temperature, single conductor 4/0 AWG

D-C Dielectric Strength

D-C dielectric strength when measured in the manner described in the foregoing is 1.5 to 2 times the 60-cycle rms strength. Typical data are shown in Table III.

Surge Voltage Strength

The surge voltage strength of type *MI* cables has been measured using a Marx circuit arranged as described by Newman and Kemppainen.[6] The procedure in general was in accordance with the American Standards Association Standard for the measurement of voltage in dielectric tests.[7] A negative (to conductor) 1.5x40-microsecond-wave surge voltage was employed; 1.5 microseconds to reach voltage peak and 40 microseconds to fall

Table III. Dielectric Strength, Type-MI Cable

Type of Cable, AWG	Room Temperature: 60 Cps, Rms Volts	Direct Current, Volts	Surge Strength, Volts, 1½x40	Switching Surge, Volts
1-*cdr* 4/0	2,800		6,000	5,000
1-*cdr* 16	2,900		6,100	5,200
1-*cdr* 9	3,500	6,900		

to one-half peak voltage. Tests were made on single-conductor cables, sizes 16 AWG and 4/0 AWG on samples approximately 10 feet long. The wave shape was observed by means of a cathode-ray oscilloscope. Measurements were conducted at room temperature. The surge voltage was initially 5,000 volts; it was raised in 5% steps until failure occurred. It has been found in surge testing that repetitive tests on the same cable sample may result in subsequent breakdowns at voltages equal to or greater than the original breakdown level. In actual service, however, a surge breakdown may cause power follow-up and permanent failure. In Table III typical surge strength data taken at room temperature are given. For comparison purposes, dielectric strengths at 60 cps are given. These were obtained following the step-by-step procedure described previously under a-c dielectric strength tests. The 1.5 x 40-microsecond surge strength of *MI* cable is about 50% greater than the 60-cycle peak voltage strength.

SWITCHING SURGE VOLTAGE STRENGTH

Switching surge voltage strength tests were made on the same *MI* cable sizes as were employed in the surge voltage tests. A switching surge which took 1,000 microseconds to reach the first peak was employed. A damped wave was used, each succeeding peak decreasing 20% from the previous one. The surge was initiated by discharging a capacitor (previously charged by d-c voltage) across the primary winding of a testing transformer. The *MI* cable specimen was connected across the secondary winding of the transformer. Wave shape was observed by means of a cathode-ray oscilloscope. Otherwise the same procedure of test was followed as described under surge voltage strength tests. The switching surge breakdown voltages are tabulated in Table III.

MECHANICAL PROPERTIES

The cable will withstand severe mechanical abuse such as bending, twisting, and impact without appreciably impairing its electrical efficiency.

Table IV indicates the reduction in dielectric strength of single-conductor 4/0 AWG cable after bending the cable at room temperature around a mandrel having three times the diameter of the cable. The dielectric strength after stretching the cable 10% of its original length at room temperature is also given. Dielectric strength test procedure was the step-by-step procedure described previously under a-c dielectric strength tests.

Another sample of 4/0 AWG cable was placed in an Amsler Universal testing machine and slowly crushed between a steel plate and a steel mandrel of the same diameter as the cable but set at right angles to it. The compressive load to cause insulation breakdown, when 1.8 kilovolts (three times the voltage rating) were maintained between conductor and sheath, was 17,500 pounds. The magnesium oxide insulation was flattened, along with the cable sheath and conductor.

Additional crushing tests comparing *MI* cable to conventional types of armored cable and wire-in-conduit are indicated in Table V. Three samples were cut from each cable, tube, or conduit under test and were placed between a flat steel plate and a V-shaped anvil hardy having a smoothly rounded edge with 1/4-inch radius, and crushed by means of a Dillon tester. The outside diameters were measured and the forces necessary to crush to one-half of the outside diameter were observed. The samples were chosen at random from various manufacturers of labeled rigid steel conduit, electric metallic tubing, and armored cable.

Table IV. Mechanical Abuse Tests, Single-Conductor 4/0 AWG

	Breakdown Voltage, Kilovolts, Rms: After Bending Around 3X Mandrel	After Stretching Longitudinally 10%
Sample *A*	2.80	2.30
Sample *B*	2.70	2.40
Sample *C*	3.20	2.50
Average	2.90	2.40
Original	3.85	3.85
Reduction, %	25	38

Impact tests were also conducted to establish the effect of a sudden blow on *MI* cable; the results appear in Table VI. These tests, in addition to *MI*, also included other conventional types of wiring systems utilizing samples chosen at random from various labeled manufacturers. In these impact tests, the cable was laid over an anvil hardy having a smoothly rounded edge with a 1/4-inch radius. Weights of 50, 20 and 10 pounds were dropped on the cable and the length of drop in feet determined which produced not more than two failures in 10 separate blows. A 3-phase 4-wire 120/208-volt a-c supply with neon lamps in the circuit was used to detect failure.

These various mechanical abuse tests indicate that type-*MI* cable has greater resistance to impact than armored cable and less than rigid steel conduit. It has greater impact resistance than electrical metallic tubing in the larger sizes, and equivalent resistance in the smaller sizes. With regard to crushing, the resistance of type-*MI* cable is greater than that of ar-

mored cable, electrical metallic tubing, and rigid steel conduit in the larger sizes; the crushing resistances of type-*MI* cable and the smaller sizes of rigid steel conduit are equivalent.

As would be expected, the breaking strength, elongation, and stress-strain properties of type-*MI* cable are essentially those of an annealed copper wire having the same cross-sectional area as the combined areas of sheath and conductor(s). Fig. 7 is a cyclic-loading stress-strain diagram for single-conductor 12 AWG type-*MI* cable. In this test, load was cyclically applied as follows:

1. Starting from an original value of 8% of the cable's ultimate strength, load was increased to 30% of the cable strength and held for 15 minutes.
2. Load was next reduced back to the original 8% value, then raised to 50% of the cable strength and held for 1 hour.
3. Once more, load was reduced to the 8% value and again raised, this time to 70% of the cable's ultimate strength, and held for 2 hours.
4. Finally, the applied load was again reduced to the 8% value, and raised to 73% of the cable's ultimate strength and held for 1 hour.
5. Thereupon the extensometer was removed and, after returning once more to the original 8% starting load, the sample pulled to destruction.

This test was performed on a 134.5-inch gauge length in an Amsler tensile machine. The rate of both load application and removal was 100 pounds per minute.

The ultimate strength of this particular type-*MI* cable was 650 pounds. Inasmuch as the cable as a whole has a cross-sectional area of 0.0475 square inch, and the combined cross-sectional area of the sheath and conductor is 0.0216 square inch, this corresponds to a tensile stress of 13,700 pounds per square inch in the cable as a whole, and of 30,100 pounds per square inch in its metal components. This latter value is quite usual for annealed copper conductors. The *MI* insulation itself, of course, has negligible strength in tension. The final modulus of elasticity indicated by Fig. 7 is 5.9×10^6 pounds per square inch based upon the entire cable, and 13×10^6 based on its metal components alone.

In Fig. 7 the cross-sectional area of the entire cable has been taken as the stress base primarily to demonstrate that the cable responds smoothly as an integral unit to changing mechanical loads. Thus presented, it should be understood that the figure is particular to single-conductor 12 AWG type-*MI* cable. However, this figure may be translated readily to one that is universally applicable to type-*MI* cables of all sizes and constructions, merely by multiplying the ordinates of the diagram by the ratio of the cable area to the metal component area, i.e., by the ratio 0.0475/0.0216.

Resistance to Corrosion

Because copper is more resistant to corrosion than most metals in common usage, type-*MI* cable can be installed successfully in most industrial locations. However, in environments containing gaseous or liquid reagents detrimental to copper, such as some chemical and processing plants, etc., the advisability of a protective covering should be considered. This might take the form of a simple coat of acid-resistant paint, neoprene jacket, or the like. The necessity of such coverings can be judged most simply and reliably by experience with copper vessels, tubing, bare conductors, etc., in the same environment. Direct burial of plain type-*MI* cable in the earth is usually inadvisable unless it is known that electrolysis and exposure to acid-reaction materials are not involved. Cathodic protection may be effective where electrolysis is a factor, and a suitable protective covering will usually provide protection against both electrolysis and chemical corrosion.

Electrical Constants

The electrical constants of interest in engineering given applications of type-*MI* cables differ little, if at all, from those of the older conventional forms of low-voltage power cables. Cable size (aside from thermal or current rating relations discussed later), voltage regulation, and operating efficiency are all calculated in conventional manner; in fact, existing voltage drop and power loss tables will be found to serve satisfactorily. Where, however, it is desired to engineer a given job with close accuracy, the following information will prove helpful.

Resistance

The conductors and sheaths of type-*MI* cables are of high-grade annealed copper and naturally have the standard resistivity and temperature coefficient of resistance of that material. In short, the d-c resistance of a given *MI* conductor

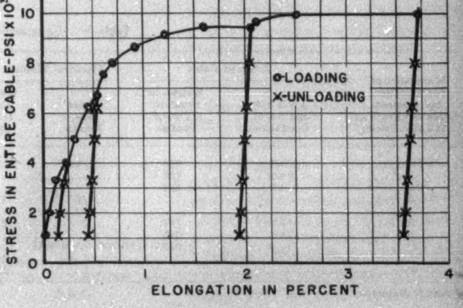

Fig. 7. Stress-strain diagram. Single-conductor 12 AWG, type-MI cable

at any given temperature is the same as that of any other good, solid, annealed copper conductor of the same size at the same temperature.

For greatest accuracy in all a-c applications, particularly in the case of the larger conductor sizes, there should be added to the d-c resistance the further effective resistance components resulting from skin and proximity effects and sheath losses. Methods for doing this are presented in the Appendix.

Contrary to first impressions in some quarters, the increased resistance of type-*MI* cables to alternating currents is moderate. Considering, e.g. a, 3-phase 60-cycle circuit composed of three single-conductor 4/0AWG *MI* cables (the largest standard size) arranged in equilateral triangular configuration with sheaths in contact and operating at a conductor temperature of 85 C, the total increment in effective conductor resistance due to combined skin and proximity effects and sheath losses is only 5.8% (see the Appendix), about the same as the resistance increase that would occur with three conventional 4/0 AWG single-conductor cables in conduit. The added losses of smaller *MI* cables, and in particular multiconductor *MI* cables, are much lower, as will be apparent from the typical examples given in the Appendix.

The principal cause of increase in effective conductor a-c resistance of single-conductor *MI* cables is, of course, the loss created by sheath-circulating currents. Inasmuch as the effect of sheath currents increases with cable spacing, it is generally desirable to group single-conductor cables of a circuit closely together if best voltage regulation and lowest power losses are important desiderata.

INDUCTIVE REACTANCE

For both multiconductor and grouped single-conductor *MI* cables, the inductive reactance from conductor to neutral is given quite simply by the following equation

$$X_1 = 0.8820 \times 10^{-3} f \log_{10} \frac{2.568S}{d} \qquad (1)$$

where

X_1 = inductive reactance to neutral, ohms per 1,000 feet
f = frequency, cps
S = effective spacing between conductor centers, inches
d = diameter of conductor, inches

The inductive reactance of *MI* cables is inherently low compared with that of older conventional cables because of relatively close conductor spacings, a factor generally helpful in improving voltage regulation, particularly at power frequencies in excess of 60 cps.

CAPACITANCE

The specific inductive capacitance of compressed magnesium oxide insulation is about 3.8, generally comparable with that of a good rubber insulation of low specific inductive capacitance. For all low-voltage, low-frequency power work, therefore, capacitance effects are of little practical significance and, as in the case of most other low-voltage cables, may be neglected. However, where operating frequencies become sufficiently high to make capacitance of possible interest, it may be evaluated by methods presented by Simmons,[8,9] Dwight,[10] and Lee.[11] Reference 8 will be found most convenient for rapid evaluation of capacitance from: 1. conductor to sheath, i.e., to neutral, for single-conductor cable; 2. conductor to neutral for 3-conductor cables; and 3. all conductors to sheath for 2-, 3-, and 4-conductor cables. Reference 9 also gives an equation for estimating the capacitance from all conductors of an *n*-conductor cable to sheath. Unfortunately, however, no satisfactory G_2 factors for 2- and 4-conductor cables (for the calculation of capacitance from conductor to neutral) have yet emerged in the literature, so far as the authors are aware, which makes it necessary to determine such capacitances empirically where required.

Temperature Capabilities

The temperature capabilities of *MI* cables are truly remarkable. Mention has already been made of the fact that the final manufacturing operation is a deep anneal, something that would be totally impossible with any other type of cable known today. Magnesium oxide insulation is stable and unaffected by temperatures up to its melting point, 2,800 C. Actually, the only temperature limit in short-time exposures is the melting point of copper itself, 1,083 C. Short of that point, *MI* cable is completely nonflammable; not only will it not burn or support combustion, but it will not develop flammable or toxic gases. In a word, it is the most nearly fireproof cable available today and, remarkably, its end temperature limit is determined not by its insulation but rather by its conductor or conductors and sheath. Its refractory properties constitute an important practical advantage for many types of applications.

The temperature limit of *MI* for continuous operation is determined only by the progressive oxidation temperature of its copper sheath. Investigation shows this to be about 250 C, i.e., provided that temperature is not exceeded, a reasonably long sheath (and cable) life may be expected. Operation at temperatures in excess of 250 C, on the other hand, appears likely to cause progressive oxidation of the sheath (oxidation, spalling of the oxide coating with expansion and contraction of the cable, and exposure of fresh metallic copper, further oxidation, etc.), and curtailed sheath life.

Pilling and Bedworth[12] have developed an equation for oxide film growth on copper in the following general form

$$W = \sqrt{Kt} \qquad (2)$$

where

W = increase in wire weight due to the combined oxygen in the surface oxide film, grams per square centimeter of wire surface
K = oxide film growth parameter (see Fig. 8)
t = time, seconds

Pilling and Bedworth give the oxide film growth parameter for oxygen from 1,000 C down to 400 C; and that for air from 1,000 C down to 700 C. The values for air obviously are less than those for oxygen. The oxide film growth parameter for copper in oxygen is reproduced in Fig. 8 from data provided by Pilling and Bedworth. To increase the usefulness of the data the growth parameter is extrapolated downward to a temperature of about 250 C. The Pilling and Bedworth equation can be translated to the following more convenient form

$$d = 21{,}100\sqrt{Kt} \qquad (3)$$

where

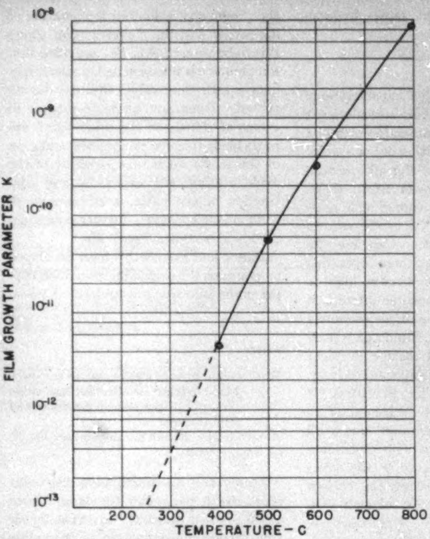
d = the thickness of copper converted to oxide, mils
K = the Pilling and Bedworth oxide film growth parameter
t = time, hours

Based on equation 3 and using the film growth parameters indicated in Fig. 8, the calculated decrease in copper sheath thickness as a function of time is given in Table VII. Values given are for oxygen and are somewhat higher than those for air; this is particularly true for temperatures in the range of 250 C.

Campbell and Thomas[13] have demonstrated that at temperatures below 250 C the rate of oxidation is somewhat less than predicted by equation 3. Their data indicate that the oxide film grows in accordance with the following general equation

$$W = \sqrt[3]{Kt + C} \qquad (4)$$

where



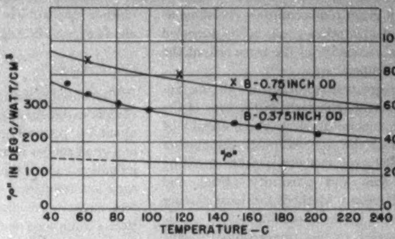


Fig. 8 (left). Oxide film growth parameter

Fig. 9 (above). Insulation thermal resistivity and sheath surface thermal resistivity as a function of temperature

W = weight of oxygen absorbed, micrograms per square centimeter
t = time, minutes
K, *C* = constants

Samples of representative type-*MI* cable were placed in an air atmosphere at temperatures of 750 and 1,000 C. The thickness of the oxide film was measured after representative periods of time. The measured decreases in wall thickness of the copper sheath are shown in Table VIII. These measured values are compared to values calculated from equation 3 with the use of the oxide film growth parameters for oxygen as presented in Fig. 8.

A design-operating temperature of 250 C is, of course, high for most ordinary cable applications (save for running through local hot spots and the like) because of deleterious effects on common building materials and hazard to personnel and, even where cable runs are suitably isolated and/or guarded, because of the heavy voltage drops and power losses associated with temperature-resistance effects, particularly for circuits of appreciable length. The resistance of copper at 250 C is 1.52 times its resistance at 85 C. This might, of course, be compensated by correspondingly larger conductor cross section, but in most instances this would be uneconomical. Most high-temperature applications of *MI*, however, are of a special nature, either involving unusually high ambient temperatures, extra-heavy current or short cable runs, or both, direct connection to electric heaters or other heat sources, or actual utilization of *MI* cable itself as a heater. All such high-temperature applications obviously require special treatment both with respect to the installation as a whole and to the necessary terminations and connections. These various considerations introduce a third operating temperature limit for *MI* in most routine applications, this time determined by ordinary practical service requirements and to an important degree by the temperature capabilities of the appurtenant terminating fittings available at present. At the moment, this latter limit is 85 C, based primarily upon the temperature capabilities of the present standard terminating fittings. This, of course, does not preclude higher local hot-spot temperatures for *MI* cables per se, provided terminations are located in cooler areas such that the combined effects of load current and ambient temperature do not cause termination temperatures in excess of 85 C. Development of terminating fittings for temperatures higher than 85 C is under way.

Table VII. Decrease in Copper Sheath Thickness as a Function of Time at Various Temperatures

Decrease in Sheath Thickness, Mils*	250 C, Years	400 C, Years	800 C, Hours
1	2.57	0.0583	0.259
2	10.3	0.233	1.04
5	64.3	1.46	6.48
10	257	5.83	25.9

*1 mil = 0.001 inch.

Current Rating

As Fig. 9 indicates, the thermal resistivity of compressed magnesium oxide insulation used in type-*MI* cables is low, being of the order of 150 C per watt per centimeter (cm)³ at a conductor temperature of 85 C, greatly facilitating flow of heat from the conductor(s) to the outer sheath.

The surface thermal resistivity of the sheath is dependent upon the degree of weathering or oxidation, upon the diameter of the cable, and apparently also to some extent upon the sheath temperature. Fig. 9 includes two curves of sheath surface thermal resistivity applicable to type-*MI* cables, one for a cable having a diameter of 3/8 inch, the other for a cable having a diameter of 3/4 inch. The surface resistivity decreases somewhat as the sheath temperature increases, but in the 80 to 85 C temperature range the indicated sheath surface thermal resistivity is about 630 and 830 C per watt per cm² for the 3/8- and 3/4-inch cable diameters respectively. The decrease of sheath surface resistivity with increasing sheath temperature may be partially explained by the blackening of the sheath (with re-

Table VIII. Comparison of Measured and Calculated Decrease in Wall Thickness, Type-MI Cable

Table IX. Dimensions of Cables Employed in Tests

Description of Cable	Conductor Diameter, Inch	Nominal Insulation Wall Thickness, Inch	Nominal Thickness of Copper Sheath, Inch	Diameter Over Copper Sheath, Inch
1-conductor 16 AWG	0.051	0.060	0.023	0.215
1-conductor 14 AWG	0.064	0.060	0.023	0.230
1-conductor 12 AWG	0.081	0.059	0.024	0.246
1-conductor 9 AWG	0.114	0.064	0.025	0.293
1-conductor 4/0 AWG	0.460	0.081	0.038	0.699
2-conductor 14 AWG	0.064	0.063	0.027	0.371
3-conductor 14 AWG	0.064	0.061	0.028	0.387
2-conductor 6 AWG	0.162	0.066	0.035	0.590
3-conductor 6 AWG	0.162	0.064	0.036	0.621
RG-81/U	0.063	0.129	0.027	0.375
RG-82/U	0.125	0.263	0.050	0.750

sultant increase of the effective emissivity factor) as the test proceeded, but it appears doubtful that this can be regarded as the sole reason. Increasing temperature would tend to increase heat dissipation both by radiation and convection.

The data presented in Fig. 9 were taken on *RG-81/U* and *RG-82U* cables having the dimensions indicated in Table IX. The cables were placed in a special chamber free of air drafts, so equipped that an ambient temperature of 40 C could be maintained. Conductor temperatures were obtained from conductor resistances measured by means of a Kelvin double bridge arranged so that the conductor resistance could be measured while the d-c loading current was passing through the conductor. The sheath was electrically idle. The sheath temperature and the ambient temperature were measured by suitable thermocouples placed along the length of the cable. The total watt input to the conductor was determined by measuring the conductor current and calculating the watts from the product of the square of this current and the conductor resistance. The insulation thermal resistivity ρ and the sheath surface thermal resistivity B were then calculated from the following equations

$$\rho = \frac{T_c - T_s}{0.00522w \log_e \dfrac{D_i}{d}}$$

$$B = \frac{(T_s - T_a)D}{0.00411w}$$

where

T_c, T_s, T_a = conductor, sheath and ambient temperatures respectively, C
D_i = diameter over insulation, inches
D = outside diameter of cable, inches
d = conductor diameter, inches
$w = I_c^2 R_{dc}$ where I_c is the conductor d-c current in amperes, and R_{dc} is the conductor resistance in ohms at the test temperature, watts per foot
ρ = insulation thermal resistivity, C per watt per cm²
B = surface thermal resistivity, C per watt per cm²

Rosch[14] has shown that the surface thermal resistivity of cables having outside diameters of about 1.75 inches and less is dependent upon cable diameter. As a result of this work the National Electrical Manufacturers' Association (NEMA) and the Insulated Power Cable Engineers Association (IPCEA)[15] have adopted a conventional standard, which has been used by the industry for many years, and in which the surface thermal resistivity of all types of cables is taken as a value varying linearly from 650 at cable diameter equal to zero, to 1,200 at cable diameter equal to 1.75 inches. For diameters larger than 1.75 inches, a constant value of 1,200 C per watt per cm² is used. Since all standard *MI* cables have sheath outside diameters of under 1.75 inches, the applicable NEMA-IPCEA surface thermal resistivity would be given by the expression

$$B = 314.3D + 650 \qquad (D \leq 1.75 \text{ inches}) \qquad (5)$$

where

B = surface thermal resistivity of sheath, C per watt per cm²
D = cable outside diameter, inches

Surface thermal resistivities indicated by equation 5 appear to be high in comparison with those indicated by the investigations of Schurig and Frick[16] on the heating of bare conductors. Fig. 10 shows two curves of surface thermal resistivity B, one a plot of equation 5, the other derived from curve A, Fig. 13, of reference 16. According to Schurig and Frick, their curve A is based on a 30 C rise above a 40 C ambient, at an indicated conductor temperature of 70 C. Also included on Fig. 10 are two test points taken from Fig. 9 of measured sheath thermal resistivity for the 3/8-inch and 3/4-inch diameter *MI* cables at a sheath temperature of 70 C. These latter points fall between the IPCEA and Schurig and Frick curves. It is evident from all of the available data that the IPCEA curve is at least on the conservative side when applied to *MI* cables, perhaps unduly so. Nevertheless it is accepted as a basis for the following estimates of current-carrying capacities for type-*MI* cables, together with the insulation thermal resistivity of 150 C per watt per cm² indicated by Fig. 9. Inasmuch as dielectric loss is negligible in type-*MI* cables, the following current-rating equations then become applicable

$$R_i = \frac{0.7832G}{n} \qquad (6)$$

$$R_s = \frac{2.672}{D} + 1.292 \qquad (D \leq 1.75 \text{ inches}) \qquad (7)$$

$$R_{th} = R_i + R_s \qquad (8)$$

$$I = \sqrt{\frac{\tau}{nR_cR_{th}}} \qquad (9)$$

where

R_i = thermal resistance of insulation, C per watt per linear foot
R_s = surface thermal resistance of sheath, C per watt per linear foot
R_{th} = total thermal resistance of cable, C per watt per linear foot
R_c = effective conductor resistance at operating temperature, ohms per foot
G = geometric factor for heat flow from conductor(s) to sheath (given for 1-, 2-, 3-, and 4-conductor cables in reference 8)
n = number of conductors in cable
τ = temperature rise of conductors, C, i.e., difference between conductor operating temperature and ambient temperature
I = current per conductor, amperes
D = cable over-all diameter, inches

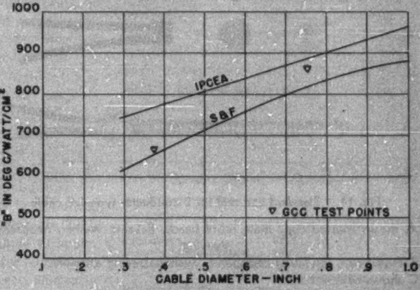

Fig. 10. Surface thermal resistivity. Comparison of IPCEA and Schurig and Frick curves and GCC experimental data

*National Electrical Code.

†Cdr = conductor.

‡Cables in triangular configuration, sheaths in contact.

These equations apply strictly to a single 1-conductor or *n*-conductor isolated cable in still air. Where several cables are grouped closely together with sheaths in contact, the group may be treated with fair approximation as a single multiconductor cable having a sheath diameter equivalent to that of the circle circumscribing the entire group. Where cables are grouped with separations between cable surfaces ranging from one-quarter to one cable diameter, the group correction factors, Table IV of reference 15 are useful. For cable groupings having spacings between cable surfaces exceeding about one cable diameter, mutual heating effects become small and may be neglected, i.e., the cables treated as individual isolated cables, without serious error.

These various considerations are subject to some modification (based upon good judgment) depending upon the physical arrangement of cable groups; for instance, vertical runs have the advantage of greater "chimney" effect than horizontal runs. Finally all theoretical calculations based on the simple assumption of cables or cable groups isolated in air necessarily involve departures from the actual conditions of many practical installations wherein cables are laid in trays, racked over surfaces, etc., and hence are affected by their surroundings. These extraneous effects unfortunately are too numerous and varied to lend themselves readily to satisfactory analytical treatment, and usually must be determined empirically.

Table X shows current-carrying capacities of type-*MI* cables calculated in accordance with the methods described. These current ratings are based upon an operating temperature of 85 C and an ambient temperature of 30 C. Current ratings for other ambient temperatures may be determined readily from the correction factors included in the table. Also included in Table X in parallel column arrangement are current-carrying capacities prescribed in the 1953 National Electrical Code for type-*MI* cables, likewise based on a conductor temperature of 85 C and an ambient temperature of 30 C. These code ratings, of course, were not determined specifically for type-*MI* cables, rather they are the ratings established earlier for other, older types of cables having the same assigned operating temperature rating, and are the category into which *MI* was placed when it received code recognition.

Terminating Fittings

As previously mentioned, magnesium oxide insulation is hygroscopic, combining with water to form magnesium hydroxide. In addition to the water of constitution, the hydroxide can also absorb a certain amount of extra water which remains in the free state. This latter tends to reduce

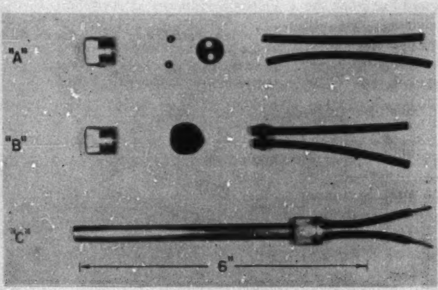

Fig. 11. Standard end seal for 2-conductor type-MI cable

the dielectric strength and current resistance of the insulation and could ultimately cause failure. However, should a cable end accidentally become exposed to moisture during handling and installation, the longitudinal penetration into the cable ordinarily is relatively slow, and confined to a short distance from the open end. In any case, absorbed moisture can be completely eliminated and the cable restored to its original dry state by playing a torch lightly over a short section adjacent to the cable end, or simply by cropping the affected end. The efficacy of such treatment can be judged most conveniently and effectively by megger test. While hygroscopic effects thus constitute no particular problem during the handling and installation stage, it will be appreciated that installed cables must be permanently sealed at their ends to prevent subsequent ingress of water. Terminating fittings are required, therefore, to serve three principal functions: 1. Seal the cable end as mentioned. 2. Provide means for extending and insulating the individual conductors beyond the cable seal for purposes of connection to terminals or other conductors. 3. Anchor the cable to the box, fitting or enclosure to which it is attached.

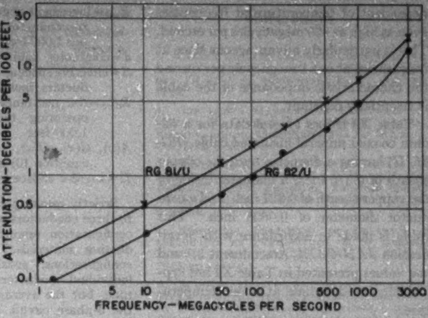

Fig. 13. Typical data showing the variation of attenuation at room temperature with frequency

Fig. 11 shows a cable seal and its component parts, in this case for a 2-conductor *MI* cable. It consists essentially of: 1. a cylindrical, knurled brass cup or pot, internally threaded at the knurled end to fit the cable sheath size for which it is intended, and having a recessed opening at the other end to receive a circular, reinforced bakelite insulating washer; 2. strain-relief insulating beads; 3. the aforementioned washer; 4. special high-temperature moisture-resistant insulating neoprene sleeving of the size required for the cable conductors; and finally 5. special plastic heat-resistant, moisture-resistant, insulating potting compound. After the sheath and insulation have been stripped from the conductors for the requisite distance (which may be much longer than that depicted in the figure), the knurled brass cup is screwed onto the end of the cable sheath, cutting its own thread in the process. The knurled cup is then completely filled with sealing compound. Next, the preassembled insulating washer and insulating sleeves (each of the latter with its strain relief bead under the washer) are slipped over the conductors and pressed home in the shouldered recess of the compound-filled knurled cup (excess compound being extruded into the sleeving and around the edges of the insulating washer), and the washer firmly secured in position by a small tool that crimps the lip of the cup thereon. This completes the cable seal proper. Seals for single-conductor and other multiconductor cables are made in identical manner except, that, aside from suitable adjustment of dimensions with those of the cable involved, the number of holes in the insulating washer and the number of insulating sleeves are co-ordinated with the number of conductors in the cable being terminated.

Fig. 12 shows the remaining components of a standard termination, which are identical in form for both single-conductor and multiconductor cables and vary only with the outside diameter of the cable involved. These components are three in number, all of brass, and consist of: 1. a threaded gland internally recessed to fit the knurled sealing cup; 2. a compression ring which fits over the cable sheath and seals it off (on the well-understood principle adapted so widely to pressure pneumatic and hydraulic tubing); and 3. a follow-up compression-locking nut. The threaded gland proper, of course, may be inserted into a box or enclosure and secured thereto by a standard locknut, or screwed into threaded bosses of various types of enclosures, in either case anchoring the cable to the device or fitting on which it terminates. Cables may be spliced, where required, by terminating them into a suitable box, and joining and insulating the conductor ends within the box. The entire standard *MI* cable line is accommodated by only four sizes of threaded glands (with associated seal ring and locknut) corresponding to conduit sizes of 3/8 inch, 1/2 inch, 3/4 inch, and 1 inch respectively. The threads of these glands are standard conduit threads.

It can be seen from this brief outline that *MI* terminating fittings are both simple in principle and simple to apply, and require no essentially new techniques. Properly installed, they very efficiently and effectively serve their intended purpose, even with standard knockout boxes and enclosures. Employment of watertight boxes and enclosures, where required, to protect otherwise exposed conductor terminal lugs, screws, etc., makes possible a completely moistureproof, vaporproof, and dustproof system.

Present standard terminating fittings have an assigned maximum continuous operating temperature of 85 C, governed by the temperature capabilities of the pot-sealing compound, insulating washer, and insulating sleeving. The possibilities of alternate potting compounds and sleevings, suitable for operation at higher temperatures, are being investigated, with currently encouraging prospects. There are also possibilities in the ceramic-soldered-to-metal type of terminal, or small cable pothead, for use under very high temperature conditions or where atomic radiation is a factor. These possibilities are being looked into and can be exploited as occasion requires.

High-Frequency Uses

The relatively low dielectric constant and the low pf of magnesium oxide make this insulation suitable for use at ultrahigh frequencies. As indicated previously, the dielectric constant is relatively constant over the frequency range of 60 cps to 400 megacycles per second. The pf is relatively constant. Both the dielectric constant and pf are practically in-

Table XI. RG-81/U High-Frequency MI Cable

Room Temperature Parameters	
Capacitance	37.1 micromicrofarads per foot
Impedance	52.5 ohms
Velocity of propagation	53.0%
Attenuation	2.1 db per 100 feet at 100 megacycles

dependent of temperature at frequencies even as high as 400 megacycles per second. This is particularly advantageous since at frequencies above 1 megacycle per second the characteristic impedance of the cable is essentially constant.

Table XI shows typical data for a 52-ohm coaxial mineral-insulated cable (*RG-81/U*) having a diameter over the copper sheath of 0.375 inch, a diameter inside of the copper sheath of 0.321 inch, and a conductor diameter of 0.0625 inch. This cable is made in accordance with Specification *JAN-C-17A*, Amendment 3,[1] and the values presented in Table XI are typical measured values at room temperature.

Measurements of attenuation on *RG-81/U* and *RG-82/U* were made at room temperature. A General Radio type-874 coaxial equipment set was used for measurements in the frequency range of 1 to 900 megacycles per second. For measurements at 3,000 megacycles per second, the *MIT CO-AX* instrument and cable test unit type *Q* was employed. Results are shown in Fig. 13.

Appendix

Skin and proximity effects and sheath losses tend to increase the effective a-c resistance of conductors in metallic-sheathed cables. Skin and conductor proximity effects are common to all cables, whether single-conductor or multiconductor. In the case of grouped single-conductor cables, sheath losses consist of two components, those due to sheath proximity (eddy) currents which flow solely within the individual sheaths, and those due to sheath-circulating currents which leave an individual sheath at one or more points and return to it at one or more others. In the case of individual multiconductor cables, sheath losses consist solely of those due to sheath proximity (eddy) currents.

Skin effect can be evaluated most conveniently by means of tables contained in most electrical handbooks[17] of a-c/d-c resistance ratios corresponding to the function

$$x = 0.02768\sqrt{f/R_{\text{d-c}}} \qquad (10)$$

where

f = frequency, cps
$R_{\text{d-c}}$ = conductor d-c resistance at operating temperature, ohms per 1,000 feet

Conductor proximity effects can be estimated by means of the following equations from Arnold[18,19]

$$R_{pc1} = 0.5K(d/S)^2 A(x) R_{d-c} \text{ (single-phase)} \qquad (11)$$

$$R_{pc3} = \frac{1.5(d/S)^2 G(x) R_{d-c}}{1 - 0.2083(d/S)^2 H(x)} \text{ (3-phase)} \qquad (12)$$

where

R_{pc1} = increment of conductor resistance due to conductor proximity effect, ohms per 1,000 feet, for single-phase circuits
R_{pc3} = increment of conductor resistance due to conductor proximity effect, ohms per 1,000 feet, for 3-phase circuits
d = conductor diameter, inches
S = effective spacing between centers of conductors, inches
R_{d-c} = d-c resistance of conductor at the operating temperature, ohms per 1,000 feet
$A(x)$, $G(x)$, $H(x)$, are functions of x (see equation 10) as given in Fig. 14
K = a-c/d-c resistance ratio (reference 17)

Strictly speaking, equation 12 applies only to three conductors in equilateral triangular configuration remote from all other conducting materials. For other conductor configurations, proximity effects on the individual conductors will differ in magnitude, but the average proximity effect for the 3-phase circuit as a whole should be indicated with practical accuracy by employing the effective conductor spacing for the particular configuration involved. Equation 11 also applies strictly only to conductors remote from all other conducting materials. Moreover, particularly in the case of grouped single-conductor *MI* cables, at least, the proximity effects indicated by both equations 11 and 12 tend to be pessimistic, i.e., too high, because these equations do not take into account sheath currents which, being of opposite polarity to the conductor currents, reduce flux linkages between conductors and hence reduce proximity effects. However, inasmuch as conductor proximity effects are relatively small for type-*MI* cables, even of the largest sizes, these equations serve with practical accuracy and tend, if anything, to be conservative.

Sheath proximity loss is attributable to eddy currents induced in the sheath by the main conductor currents. For two single-conductor type-*MI* cables connected in a single-phase circuit, the sheath proximity loss may be calculated from the following development of an equation from Arnold[20]

$$R_{ps1} = \frac{73.4f^2}{R_s}\left(\frac{D_m}{2S}\right)^2 \times 10^{-9} \qquad (13)$$

where

R_{ps1} = increment of conductor resistance, ohms per 1,000 feet
R_s = sheath resistance at operating temperature, ohms per 1,000 feet
f = frequency, cps
D_m = mean sheath diameter, inches
S = spacing between conductor centers, inches

For three single-conductor type-*MI* cables arranged in equilateral triangular configuration and carrying balanced 3-phase currents, the sheath proximity effect may be calculated from

$$R_{ps3} = \frac{110f^2}{R_s}\left(\frac{D_m}{2S}\right)^2 \times 10^{-9} \qquad (14)$$

where R_{ps3} = increment of conductor resistance, ohms per 1,000 feet, and the other symbols are the same as given for equation 13.

For three single-conductor type-*MI* cables arranged in a flat configuration, the effect of the sheath proximity losses may be calculated from the following equations from Arnold[20]

R_{ps3} (either outer cable)

$$= \frac{55f^2}{R_s}\left(\frac{D_m}{2S}\right)^2 \times 10^{-9} \qquad (15)$$

R_{ps3} (middle cable)

$$= \frac{220f^2}{R_s}\left(\frac{D_m}{2S}\right)^2 \times 10^{-9} \qquad (16)$$

where symbols are the same as given for equation 13.

The effect of sheath proximity loss for a 2-conductor type-*MI* cable may be calculated from the following equation, which is a development of a similar equation originally developed by Meyerhoff[21]

$$R_{ps1}' = 1.913 \times 10^{-4} f M_{21} \qquad (17)$$

where

R_{ps1}' = effective increase in conductor d-c resistance, ohms per 1,000 feet

$$M_{21} = 4v\left(\frac{a^2}{1+V^2} + \frac{a^6}{9+V^2} + \frac{a^{10}}{25+V^2} + \ldots\right)$$

$$a = \frac{d(m+1)}{D_m}$$

$$v = \frac{1.913 \times 10^{-4} f}{R_s}$$

m = ratio of insulation thickness (as previously defined) to conductor diameter
f, d, D_m, and R_s have the meanings given previously

In the case of 3-conductor type-*MI* cables, the effect of sheath proximity currents can be evaluated by means of the equation suggested by Simmons[8]

$$R_{ps3}' = \frac{396(2S_1)^2}{R_s D_m^2} \times 10^{-6} \qquad (18)$$

where

R_{ps3}' = effective increase in conductor resistance, ohms per 1,000 feet
S_1 = distance between center of each conductor and center of cable, inches
and all other symbols have the meanings previously given

For two single-conductor cables in a single-phase circuit or three single-conductor cables with equilateral spacing in a 3-phase circuit, the added effective conductor resistance due to sheath-circulating currents is given by the relations

$$R_0 = \frac{X_m^2 R_s}{X_m^2 + R_s^2} \qquad (19)$$

$$X_m = 0.8820 \times 10^{-3} f \log_{10}\frac{2S}{D_m} \qquad (20)$$

where

R_0 = added effective conductor resistance, ohms per 1,000 feet
X_m = mutual reactance between conductor and sheath, ohms per 1,000 feet
S = effective separation between cable centers, inches
R_s, f, and D_m have the meanings assigned previously

Equations 19 and 20 apply rigorously only when sheath proximity effects are negligible. In most practical problems, however, the error is relatively small,

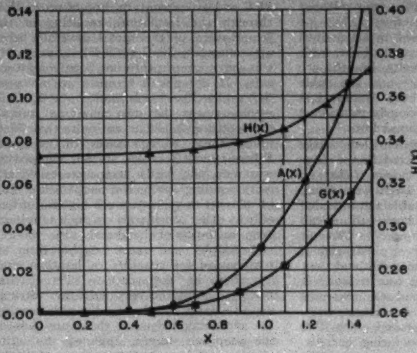

Fig. 14. Functions of x for determination of conductor proximity effects

though it is a maximum for the case of cables with sheaths touching. A more exact evaluation in such cases has been worked out by Miller[22] and Dwight.[23,24]

For other arrangements of one and two circuits of single-conductor cables, see Table VI of reference 8.

The application of these equations to type-*MI* cables may best be shown by a few typical examples. Consider first a 60-cycle 3-phase circuit composed of three single-conductor 4/0 AWG type-*MI* cables arranged in equilateral triangular configuration with sheaths in contact and operating at a conductor temperature of 85 C. For these cables the following data are applicable

$R_{d\text{-}c}$ at 85C = 0.0615 ohm per 1,000 feet
$d = 0.460$ inch
$S = 0.699$ inch
$R_s = 0.127$ ohm per 1,000 feet at an assumed temperature of 80 C
$D_m = 0.661$ inch

$$x = 0.02768\sqrt{\frac{60}{0.0615}} = 0.864$$

From handbook tables of a-c/d-c resistance ratios, the ratio corresponding to the value of x in the foregoing is 1.0029. In short, 60-cycle skin effect increases the resistance of the conductor by 0.29% or 0.0002 ohm per 1,000 feet.

For conductor proximity effect, $G(x)$ and $H(x)$ are 0.0085 and 0.338 respectively, as obtained from Fig. 14. Then

$$R_{pc3} = \frac{1.5\left(\frac{0.460}{0.699}\right)^2 0.0085 \times R_{d\text{-}c}}{1 - 0.2083\left(\frac{0.460}{0.699}\right)^2 0.338}$$

$$= 0.0057 R_{d\text{-}c} = 0.0004 \text{ ohm per 1,000 feet}$$

which is equivalent to an increase of effective resistance of 0.57%.

For sheath proximity effect

$$R_{ps} = \frac{110 \times (60)^2}{0.127}\left(\frac{0.661}{2 \times 0.699}\right)^2 \times 10^{-9}$$

$$= 0.0007 \text{ ohm per 1,000 feet}$$

which corresponds to a 1.14% increase in the d-c resistance value of 0.0615.

The effect of sheath circulating current is given by

$$X_m = 0.882 \times 10^{-3} \times 60 \log_{10} \frac{2 \times 0.699}{0.661}$$

$$= 0.0172 \text{ ohm per 1,000 feet}$$

$$R_0 = \frac{(0.0172)^2 \times 0.127}{(0.0172)^2 + (0.127)^2} = 0.0023 \text{ ohm per 1,000 feet}$$

which corresponds to an increase of 3.73% in the conductor d-c resistance.

The total 60-cycle resistance at 85 C is therefore = 0.0615 + 0.0002 + 0.0004 + 0.0007 + 0.0023 = 0.0651 ohm per 1,000 feet or 105.8% of the d-c resistance. This is commensurate with resistance increase occurring with three conventional 4/0 AWG single-conductor cables in conduit.

The example given purposely involves the largest standard size of single-conductor *MI* cable. The added losses of smaller cables and, in particular, multiconductor cables, are much lower. For instance, for size 4 AWG single-conductor cables in equilateral triangular configuration with sheaths in contact, the skin and proximity effects are negligible and the added conductor resistance due to sheath circulating currents is only 0.33% of the d-c resistance, assuming as before a conductor operating temperature of 85 C and a frequency of 60 cycles.

The added losses in the case of multiconductor type-*MI* cables are still lower. For 3-conductor 4 AWG type-*MI* cable (the largest standard size) operating at a temperature of 85 C and a frequency of 60 cycles, skin and conductor proximity effects again are negligible and the increased effective resistance due to sheath proximity currents is indicated as

$S_1 = 0.157$ inch
$R_s = 0.118$ ohm per 1,000 feet at an assumed temperature of 80 C
$R_{d\text{-}c} = 0.312$ ohm per 1,000 feet at 85 C
$D_m = 0.691$

$$R_{ps3}' = \frac{396(2 \times 0.157)^2 \times 10^{-6}}{0.118 \times (0.691)^2} = 0.000693$$

This corresponds to an increase in conductor d-c resistance of only 0.22%, a very small value.

◆

Discussion

Henry Richter (Ebasco Services, Inc., New York, N.Y.): This type of cable is coming into wider use for power, control, lighting, and heating tracers for freeze protection. For the first three of these applications the considerations leading to its choice may include fire hazard, ruggedness, lower installed cost than the more or less standard cables in conduit, high ambient temperatures, etc. In freeze protection circuits it may be called upon to withstand one of the worst possible conditions for insulated cables, namely, the presence of moisture and temperatures up to 250 C, or 482 degrees Fahrenheit (F).

Based on our experience with type-*MI* cables in all four of the applications just listed, it would appear that improvements in the terminations would assist materially in furthering the use of this cable, and the following remarks are directed mainly toward that end.

In the section "Properties of Magnesium Oxide Insulation," it is stated that "The presence of free moisture quickly reduces the dielectric strength and allows an appreciable leakage current to flow." A test was made using two pieces of *MI* cable with the conductors spliced and the ends of the magnesium oxide left exposed to the air. This joint was enclosed in a large conduit box with water in the bottom of the box to a depth of about 1/4 inch, the joint being about 1/4 inch above the water. The box was then hermetically sealed. The magnesium oxide thus was subjected to almost a completely saturated atmosphere. Readings of insulation resistance were taken daily and the test was continued for 90 days at room temperature. The insulation resistance dropped from an initial 200,000 ohms to as low as 20,000 ohms after several days, then climbed steadily to approximately 80,000 ohms after several weeks and continued there for the remainder of the test. If the two ends of a cable on a 480-volt circuit supplying a motor were similarly exposed to extremely high humidity it would thus appear that the maximum leakage current due to low insulation resistance would be about 20 milliamperes.

It is noted in the section "Terminating Fittings" that in the presence of moisture the mineral insulation forms magnesium hydroxide, and we are informed that this compound acts as a stop to the entrance of moisture into the magnesium oxide insulation beyond the hydroxide. This may explain why the insulation resistance of an *MI* cable exposed to moisture-saturated air for a very long time is not lower than has been noted.

At the end of the 90-day exposure, potentials of 120 volts a-c and d-c, 240 volts a-c and d-c, and 440 volts a-c and d-c were applied successively to this joint without failure or any noticeable effects. The a-c voltage was then increased in steps until flashover occurred at the end of the cable at approximately 1,500 volts, but the arc left no noticeable damage and the cable undoubtedly could have been continued in service at any of the previously mentioned operating voltages after breakdown.

Again, in the subsection entitled "Surge Voltage Strength," it is stated that a surge breakdown may cause power follow-up and permanent failure. Tests were made with a typical type-*MI* cable the unsealed end of which had been immersed in tap water for 50 days continuously, 120-volt alternating current was applied and a small arc occurred at the cable end, but when the circuit breaker was reclosed it did not trip. The cable end was immersed in water again, but for 5 minutes only. This procedure was repeated with 220 volts and 440 volts alternating current. There was no visible damage to the cable. The worst kind of fault that might be encountered in service was then reproduced at the end of the type-*MI* cable by completely coating the magnesium oxide with heavy carbon black, and thoroughly moistening the latter. This fault produced a loud report on 440 volts alternating current but all of the carbon black was burned off and the type-*MI* cable termination was left unimpaired. When the circuit breaker was reclosed there was no further trouble. The fault current in this case was limited by the relatively small capacity of the source of potential. It may be that with the heavy follow currents available from control and auxiliary power busses in generating stations an arc would result in the spattering of copper at the end of the magnesium oxide insulation, which would bridge the gap between conductors or between conductor and sheath and thus produce permanent failure, but such evidence is still to be produced.

As regards switching surges, which may reach 5,000 to 7,000 volts on control and auxiliary power circuits in generating stations and thus cause flashover at sealed as well as unsealed ends of type-*MI* cable, there are rather simple and inexpensive methods for suppressing such surges when the source of the trouble has been located. For example, a resistor, capacitor or small rectifier may be shunted across the relay coil or solenoid that gives rise to the surge. It seems still to be proved that switching surges will be of consequence in producing permanent failure of type-*MI* cables in generating stations even if the cable ends are not sealed.

In the subsection "Resistance to Corrosion," a maximum copper temperature of 85 C is noted for the more usual circuits. The temperature drop through the insulation is not likely to exceed 5 C with the conductor at 85 C, which would give a sheath temperature of 80 C (176 F). Such a sheath temperature would be excessive as regards safety to personnel if the cable is installed where it may be touched readily by workmen. In some cases the temperature of bare metal surfaces exposed to personnel in generating stations is limited to 60 C (140 F). However, lead-covered cables and armored cables have been in service in such stations for many years with maximum copper temperatures of 85 C and a temperature drop of up to 15 C through the insulation, resulting in the temperature of the metal covering being approximately 70 C (158 F). Apparently this outer temperature has been considered safe. If the sheath temperature of type-*MI* cables likewise is limited to 70 C it would appear that the maximum copper temperature should be not more than 75 C under these circumstances of exposure. Where type-*MI* cables are not exposed to workmen, the sheath temperature and the corresponding conductor temperature may be allowed to go very much higher, limited only by other considerations, such as voltage drop, oxidation of the sheath, etc.

A simpler and more reliable form of termination for type-*MI* cables than that described in the section "Terminating Fittings" would be very welcome. Stringing the beads on the conductors, forming the anchoring bulges at the inner ends of the neoprene sleeves, applying the quite plastic insulating potting compound to the brass sealing cups, and threading the washer over the numerous conductors and securing it in the cup are fussy operations for workmen. Furthermore, at an ambient temperature of 100 F or higher, such as encountered in the central and southern parts of the United States during the summer, the potting compound quickly flows out of the sealing cup when the cable is vertical and the cup mouth is downward. It may thus be difficult to keep the cup filled with compound until the washer has been secured in place at the mouth of the cup. With regard to stripping the sheath of the type-*MI* cable, it is desirable that a sheath-stripping tool for quick and easy removal of the sheath be made available.

Where type-*MI* cable is chosen because of its unusual quality in resisting fire, it is logical to require that the cable termination be able to withstand as high a temperature as the cable itself, namely 1,083 C (1,981 F), which is the melting point of the copper sheath. It is manifest that the type of cable termination described in the section "Terminating Fittings" would not meet this need.

Work is going forward further to introduce improvements in the terminations and applications of type-*MI* cable, which should facilitate its use greatly where its particular advantages make it superior to other types of cable.

The manufacturer of this radically new type of cable is to be commended for making it available, and the authors of the paper are to be congratulated for the thoroughness of their presentation.

S. J. Rosch (Anaconda Wire and Cable Company, Hastings-on-Hudson, N.Y.): I has been my privilege to have followed the history of the *MI* cable and to have seen an actual installation of several types on board a French battleship. Pyrotenax, as the *MI* cable is known in Europe and Canada, has had a fairly successful operating record and meets an indicated need under certain operating conditions. That was one of the main reasons for its broad acceptance as one of the permitted wiring methods in the 1953 edition of the National Electrical Code[1] and if used within the temperature limitations of 90 C maximum, it should perform satisfactorily under the various conditions for which it is now recognized.

It is for this reason that exception is taken to the statement by one of the authors that, given the proper type of termination, it should be possible to operate the *MI* cable at temperatures up to 250 C. It should be noted that the current-carrying capacity ratings in Tables 1 and 2 of the National Electrical Code[1] are based on continuous duty. Whereas it is possible that the magnesium oxide insulation may be operated continuously at temperatures up to 250 C, the same is not true of the over-all copper sheath or the copper conductors. From a metallurgical point of view, copper may not be operated continuously at temperatures in excess of 150 C. The term "copper" as used in the present discussion, does not include special copper alloys intended for higher-temperature operation.

Many electrical people have observed embrittlement of copper conductors connected to the base of certain gas-filled lamps. Actual measurements at the base of such lamps indicated temperatures of about 400 F (approximately 200 C). One of the solutions offered, is the use of nickel or nickel-clad copper conductors for such cases and is so stated in the Underwriters' Laboratories' standard for *AF* fixture wire.[2] When an *MI* cable should operate continuously at a conductor temperature of 250 C, the temperature of the over-all copper sheath would undoubtedly be in excess of 200 C. This combination is a condition which I consider unsafe for continuous operation, hence this word of caution. It should be noted that this general subject, the maximum safe permissible operating temperature for both copper and aluminum, is now under consideration by a special code committee.

E. G. Davies (Pyrotenax of Canada, Ltd., Toronto, Ont., Canada): In presenting this excellent paper on *MI* cables, Dr. Eager touched upon the hygroscopic nature of the insulant (magnesium oxide), but in the event that this may cause some doubts concerning the performance of these cables, attention is called to an important fact relating to this characteristic. In the normal course of installing this cable, and assuming that a length or coil has been exposed to the atmosphere for some time, the electrician in stripping away the copper sheath from the ends, to produce the required lengths of conductor tails, automatically frees the end sections of the insulation, thus returning from magnesium hydroxide to the original magnesium oxide, and a megger test on a run of *MI*. Cable thus prepared for terminating in the prescribed manner, will produce a reading of infinity.

The rigidity of these cables has been mentioned, but it should be noted that the experience referred to was in connection with a somewhat special size (outside the normal range in which these cables are produced) in fact, something in excess of 1-inch outside diameter. The flexibility of *MI* cables throughout the listed range is considered adequate for the majority of applications, and it will be noted that a radius of six times the diameter has been prescribed and approved by the National Electrical Code. (See reference 1 of Mr. Rosch's discussion.)

Replying to the remarks of Mr. Rosch, who appears to be keenly interested in striving for a temperature limit of 150 C for copper, it is to be hoped that he will not overlook the requirements demanded by certain branches of industry in such applications as vessels, machines, etc. in which lighting circuits are required to function in temperatures well in excess of 150 C. For these applications *MI* cables with suitable high-temperature terminating fittings will prove most advantageous.

An incident of World War II in England serves to prove the general robustness of *MI* cables. During a severe air raid over London, a bomb was dropped on an oil refinery on the Thames River, and the feeder cable (mineral-insulated) running under the jetty and over a section of the river was put out of commission. Upon examination it was discovered that a bomb fragment had passed under the jetty, sheering off a section of the copper sheath of the no. 4/3 conductor *MI* cable (0.730-inch outside diameter). By the application of a blow torch for a few inches either side of the fracture, thus driving out whatever moisture had penetrated the insulation, it was a simple matter to solder over the fracture, and in a very short time the cable was in service again.

C. A. Jordan and **G. S. Eager, Jr.**: Mr. Richter indicates that improvements in the terminations for type-*MI* cable would assist in furthering the use of this cable. This is recognized, and it is anticipated that future improvements will result ultimately in terminals easier for workmen to install as well as terminals suitable for operation at temperatures above 85 C. In addition, it is anticipated that improved tools to facilitate the installation of terminals will be made available. Mr. Richter's data concerning cable without terminals are extremely valuable, and they emphasize that magnesium oxide insulation, even though hygroscopic, can withstand substantial exposure to moisture and still maintain reasonable good insulating properties. The use of terminals, consequently, not only increases the margin of safety, but in addition maintains the insulation at the ends of the cable at its original insulating properties even though exposed to humidity and moisture for long periods. Mr. Richter's point concerning surge protective devices is well taken. Experience has indicated that such devices are seldom necessary on a-c circuits. For d-c circuits where voltages are 110 volts or higher, precautions may have to be taken to reduce surge voltages below the withstand values indicated.

Mr. Davies emphasizes that in making a normal installation, sufficient insulation is removed from the cable ends to ensure that the cable actually installed has insulation which has not been subjected to moisture ingress. The wartime experience enumerated by Mr. Davies is a typical example of how moisture, even though it may enter the cable due to a ruptured sheath or poor terminal, will not penetrate far because the magnesium oxide changes to magnesium hydroxide. Both the crystal structure and specific volume change, and the magnesium hydroxide formed acts as a seal to further water penetration. Experience shows that from 6 to 8 inches of the magnesium hydroxide acts as a good seal. The "fault" is thus restricted to a short section of the cable. This "sealing" action has been pointed out by Mr. Richter as well as by the authors.

Mr. Rosch's concern about the suggested maximum operating copper temperature of 250 C must not be taken lightly. His example, however, pertains to fixture wire and hinge cable where individual copper strands are in the order of 5 to 10 mils in diameter. Progressive oxidation is a surface phenomenon largely independent of wire diameter. Oxidation of metallic copper to a depth of, say, 2 or 3 mils would have a far more serious effect on a 10-mil wire (36 to 16% remaining area) than on a 100-mil wire (92 to 88% remaining area). We do not feel that this experience is applicable to type-*MI* cable where the copper sheath diameters and thicknesses are both considerably higher, and where the smallest conductor wire size is 16 American Wire Gauge (51 mils in diameter). Except at the ends of the cable, the copper conductors are not exposed to the atmosphere which is an additional factor in reducing any tendency towards excessive conductor oxidation. In our experience, continuous operation at a temperature of 250 C will not of itself produce embrittlement of copper.

D-C Machines—Method for Short-Circuit Calculations

JOHN CYBULSKI

JOHN P. O'CONNOR
MEMBER AIEE

IN THE U. S. Navy, problems of space, weight, reliability, and safety of electric power systems are important on the large vessels and become critical within the submarine. An optimum design with adequate protection becomes the prime goal whenever electric dynamos and their associated equipment are employed by the U. S. Navy. However, a power system of large kilowatt capacity when subjected to a fault can cause extensive damage to the bus structures, machine shafts, and circuit breakers, and possibly can disable the d c machine through flashover. In addition, the reliability of an entire system is endangered if there is incorrect circuit-breaker selectivity. On the other hand, a d-c power system which is overdesigned with a high safety factor because of lack of knowledge is also undesirable.

Because of the design advances made on d-c propulsion systems, an investigation was authorized for the study of the performance of submarine propulsion and auxiliary power equipment. Specifically, the following information on the rotating machinery was desired.

1. Maximum short-circuit current.
2. Rate of rise and decay of the short-circuit current.
3. Effect of changes in voltage, speed, and machine loading on the short-circuit characteristics.
4. Flashing characteristics.

In 1947, methods[1,2] were employed and were found to yield rather high values of short-circuit current in the Navy d-c power systems. To determine the validity of these results, the investigation was begun at the New London Naval Base where a mockup of a submarine electric system was studied under severe short-circuit conditions. Interim reports outline the experimental setup and contain the original data, progress, and development of this preliminary study. At the conclusion of this study, Naval Research Laboratory reports described the transient characteristics of d-c motors and generators, the transient characteristics of lead-acid submarine batteries, and the flashing of d-c machines caused by short circuit.[3,4]

In view of the difference between experimental and computed values of short-circuit currents using the available techniques, it was necessary that the theory of transient characteristics of d-c machines be extended to provide the accuracy necessary for attaining the optimum in shipboard system design. Although the factors contributing to the limitation of short-circuit current, namely, armature and external circuit resistance, brush-contact drop, reactance voltage, and flux distortion and destruction, were all considered, the application of these in calculating transient response from machine constants appears inadequate.

Linville[2] simplified his analysis and proposed a new method for plotting the transient currents.[5] It was still evident that more fundamental knowledge of rotating machinery was required before relations could be formulated to calculate with the required accuracy the transient response of d-c machines. A report[6] has been published which contains plots of the zero short-circuit transient resistance versus the kilowatt- or horsepower-speed product for a wide range of d-c machines. The application of these curves is suitable for estimation purposes. More recent literature contains material on related phases of this problem.[7–12] Investigation of the basic phenomena occurring during transients led to interim reports on the behavior of flux, coefficients of induction, and armature-winding resistance and brush-contact drop.[13] The purpose of this paper is to introduce new relationships to provide greater accuracy in the calculation of short-circuit current flow in d-c machines.

Nomenclature

Upper case letters denote total quantities. Exception is made for flux and flux linkages where the same size letter is used. Lower case letters denote per-unit (pu) quantities; total quantities divided by their respective base values result in a pu system.

A_t = mean section area of armature tooth, inches squared
a = number of parallel paths in the armature
B = total number of commutator segments
b = width of brush contact face in commutator segments
c = machine constant, $PZ/a\ 60$
d_s = depth of armature slot, inches
E = armature generated voltage, volts
E_r = average reactance voltage per coil, volts
F = initial over-all flux-fringing factor, approximately 1.1
g = main pole average air gap, inches
I = current, amperes
i = instantaneous current either armature or shunt field; expresses total or pu current depending on terms in the expression
K = coefficient of coupling between two circuits
K_{fs} = shunt-field mutual leakage-linkage ratio n_{fs}/n_g; for generalized values see Appendix II
K_t = permeance of the air-gap line, pu; generalized value 1.3
K_l = plus and minus sign for initial motor and generator action respectively, $1 \pm (i_{a0}/10e_0)$
K_s = steady-state load coefficient, $1-(1/3e_0)$
K_1 = permeance constant of the iron flux,[5] pu; $\phi_t/(P_a/P_p)m_{a1} - n_{b1}$
K_2 = permeance constant of the space flux,[5] pu; $1.25K_t g/(g+d_s)$
K_3 = direct armature-demagnetizing factor at steady state, $(K_s b P m_{a1})/B$
K_3' = direct armature-demagnetizing factor at peak armature current; equation 10
L = inductance, henrys
L_{g1} = inductance of shunt-field winding per pole caused by direct axis flux linkages, henrys; equation 59
L_l = inductance of shunt-field winding per pole caused by leakage linkages, henrys; equation 60
l_d = axial shunt-pole depth, inches
M_{f-a} = initial coefficient of mutual induction between the armature and shunt field, henrys; equation 27
M_{f0} = initial shunt-field magnetomotive force (mmf), $N_f i_{f0}$, ampere-turns
M_{fs0} = initial net shunt-series mmf $(M_{f0} - M_{s0})$, ampere-turns
M_{f-a}' = coefficient of mutual induction between armature and shunt field at peak time, henrys; equation 31
N = speed of machine, revolutions per minute
N_a = armature turns per pole, $Z/2\,a$
N_b = pole-face winding turns per pole
N_f = shunt-field winding turns per pole
N_s = series-field winding turns per pole
N_a' = effective number of armature-winding turns for direct demagnetization action upon the air gap as a result of an effective brush shift
n = initial coefficient of leakage between armature and shunt-field circuits
n_f = leakage-linkage coefficient for the shunt-field winding, shunt-field leakage flux linkages divided by air-gap shunt-field linkages at M_{f1}

Paper 55-112, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 24, 1954.

JOHN CYBULSKI and JOHN P. O'CONNOR are with the Naval Research Laboratory, Washington, D. C.

n_s = speed at which no-load saturation is taken, pu
n_t = number of armature teeth per pole arc
P_a = initial permeance of tube a, webers per ampere-turn
P_b = initial permeance of tube b, webers per ampere-turn
P_g = permeance of the air-gap line at no load, webers per ampere-turn
p = steady-state permeance $(K_1/3e_0+K_2;\ p \leqq K_1)$, pu
P = number of poles
p_a = pole arc, inches
p_0 = initial permeance of air gap, pu; $\phi_0(i_{f0} \pm m_{s1}i_{a0})$; plus and minus sign for cumulative and differential connection respectively
p_p = pole pitch, inches
p' = effective air-gap permeance at i_a', (K_1r'/e_0+K_2)
$\mathcal{P}$ = permeance, webers per ampere-turn; generally appears as P with subscripts and superscripts
$r = r_w + r_b + r_e$, actual resistance of armature circuit at steady-state short-circuit current, pu
r_b = effective brush-contact resistance at steady-state short-circuit current, pu; $(n_0K_s^2E_rb+V_c)/E_1$
$r' = r_w + r_b' + r_e$, actual resistance of armature circuit at peak short-circuit current, pu
T_a = initial armature-circuit time constant, seconds; equation 25
T_d = decrement time constant, seconds
T_r = rise time constant, seconds
t_{pa} = time to peak armature current, seconds
V_b = total effective brush-contact drop per unit current, volts
V_c = normal total brush-contact drop, usually 2 or 3 volts
Z = number of armature conductors
$\alpha = n_0K_i^2E_rb$, reactance voltage pu current at peak armature current
$\beta = 1/T_d$, decrement factor, seconds
$\gamma = 1/T_r$, rise factor, seconds
$\Delta\mathcal{P}$ = incremental permeance proportional to a slope on no-load saturation curve
μ = permeability of air, $4\pi 10^{-7}$, henry per meter in a subrationalized meter-kilogram-second system
ϕ_a = initial flux in tube a, webers; P_aM_{f0}
ϕ_b = initial flux in tube b, webers; P_bM_{f00}
ϕ_{fa} = effective initial mutual flux linking all of shunt-field winding turns N_f per pole, webers; as created by armature-circuit direct-axis mmf
ϕ_t = iron flux for intrinsic saturation $(A_tn_t\ 125{,}000)/\phi_1$, pu
ϕ_0 = initial air-gap flux, e_0/n_0, pu; or in lines as applicable in Appendix I
ϕ_d' = direct-axis flux at peak armature current, pu; equation 11, or in lines as applicable in Appendix I
ψ_0 = initial flux linkages of shunt field, equation 42

SUBSCRIPTS

a = external armature circuit current
b = effective brush contact
c = cable, circuit breaker
d = total armature circuit
e = external to machine winding including the short circuit
f = shunt-field circuit
0 = initial condition
s = series-field winding
w = armature winding and all other machine windings in series
x = loss of air-gap flux resulting from direct magnetization plus crossmagnetization
1 = base quantity; with mmf other than M_{f1} taken at base armature current

Prime indicates value of quantity corresponding to peak armature current. Where there is no subscript or superscript, quantity corresponds to steady-state condition. Exception is made for initial inductances and mutual.

Derivation of Equations

The over-all approach in the solution of short-circuit transients, as presented in this paper, has been to develop a method for obtaining peak armature current and the corresponding field current. Then by using these values of current and the rise and decrement factors, the transient armature and field current are found.

In the development of equations the pu system has been used. The use of the pu system is dictated by convenience and by the desire to employ the same nomenclature previously used in treating the subject of short-circuit calculations. The value of any quantity in pu is obtained by dividing the quantity by its base value.

Base values for the quantities used are:

I_{a1} = base armature current, the armature current for which the reactance voltage has been determined
N_1 = base speed, speed at which the reactance voltage has been determined
M_{f1} = base mmf, the shunt-field mmf per pole at which n_f has been determined (no load)
I_{f1} = base field current, the shunt-field current corresponding to base field mmf
ϕ_1 = base flux, air-gap flux per pole corresponding to base field mmf
E_1 = base voltage, voltage generated at no load, base flux, and base speed
R_1 = base resistance, E_1/I_{a1}

The base armature current and the base speed usually correspond to a name-plate rating at which the reactance voltage has been determined. The reactance voltage for a machine with several name-plate ratings is determined at that rating for which the product of speed and current is a maximum. In general, n_f is determined at a value of shunt-field mmf that represents maximum operating air-gap flux.

EQUATIONS FOR PEAK ARMATURE CURRENT

The peak short-circuit current of a d-c machine can be written as

$$i_a' = (e_0 - e_x')/r' \tag{1}$$

where e_0 is the initial generated voltage of the machine before short circuit and r' is the total resistance at peak current. The drop in initial generated voltage at peak current caused by the loss in air-gap flux is represented by e_x'. If e_x' is defined by the equation

$$e_x' = r_x'i_a' \tag{2}$$

then equation 1 may be written as

$$i_a' = e_0/(r' + r_x') \tag{3}$$

In equation 3 all the factors tending to reduce the magnitude of the peak short-circuit current are expressed in terms of resistance and the applied voltage e_0. By writing equation 3 in a concise form, the peak armature current is

$$i_a' = e_0/r_d' \tag{4}$$

where

$$r_d' = r' + r_x' = r_w + r_e + r_b' + r_x'$$

The problem of determining i_a' now becomes one of obtaining r_b' and r_x' in terms of known machine constants In the derivation of equations the following assumptions have been made:

1. The theorem of constant flux linkages can be applied, with negligible error, to the shunt-field linkages up to the time of peak armature current.
2. The change in permeance of the air gap from its initial value can be attributed to saturation of the armature teeth alone.
3. Armature crossmagnetization caused by initial load has negligible effect on the permeance of the air gap.
4. The brushes are on neutral and any initial load will not result in an effective brush shift.
5. There is negligible change in speed of the machine from the initial speed up to the time of peak armature current.

The derivation of equations for the effective brush-contact resistance r_b' and for the total demagnetization factor, r_x' are similar in some respects to the derivations given by Linville.[2,3] The equations given here, however, include the effect of initial conditions on the magnitude of peak short-circuit current. In addition, there is a factor in the equation for shunt-field current which reflects the effect of the series field on the transient shunt-field current.

EFFECTIVE BRUSH-CONTACT RESISTANCE r_b'

With no Initial Load

In the steady-state operation of a d-c machine where there is overload or where the commutating flux is insufficient to give good commutation, it is well known that the center of current collection shifts in the direction of rotation toward the trailing brush edge. This effective brush shift results in a direct armature demagnetizing effect on the shunt field equal to the number of armature ampere-turns included in twice the angle of shift. A second result is an increase in the effective brush-contact drop which is related approximately inversely to the time in which commutation must take place. The ordinary reactance voltage E_r is based upon linear commutation over the complete brush width. On the other hand, if commutation is assumed to take place linearly over a distance of one commutator segment (at the trailing brush tip), the reactance voltage becomes E_rb, where b is the number of commutator segments spanned by the brush. The effective brush-contact resistance in pu at any given speed is then

$$r_b' = V_b/E_1 = (n_0E_rb + V_c)/E_1 = (\alpha + V_c)/E_1 \qquad (5)$$

The reduction in the time of commutation (from the time required for the commutator to travel one brush width to the time required to travel one commutator segment) is made on the assumption that the actual nonlinear commutation existing during short circuit can be represented as a linear commutation occurring in this reduced time. This results in a uniform current density in the brush over a width of one commutator segment and zero current density over the remainder.

Actually, the current distribution in the brush face under conditions of poor commutation is small at the leading brush tip and large at the trailing brush tip. An exponential distribution of current in the brush face would appear to approach more nearly the actual distribution. Linville,[3] by solving the basic equation of a coil undergoing commutation, shows that the current density in the brush face is exponential and derives the following equation for effective brush-contact resistance

$$r_b' = V_b/E_1 = \alpha/E_1\left(\frac{\epsilon^{\alpha/V_c}+1}{\epsilon^{\alpha/V_c}-1}\right) + V_c/E_1 \qquad (6)$$

It will be noted that equation 6 is similar to equation 5. The expression in parentheses in equation 6 is essentially a correction factor. When α/V_c is large, the correction factor approaches unity and equation 5 could then be used for calculating r_b'. For simplification in computation, the effective brush drop in volts, pu current V_b, is plotted in Fig. 1 as a function of α, with V_c as a parameter. It will be noted from Fig. 1 that, as α increases, r_b' can be expressed by the more simple relation given by equation 5. In the modification of equation 6 to include the effect of initial load, it will be shown that α as defined by equation 5 is only a special case for zero initial load and a more general expression will be given in the following section.

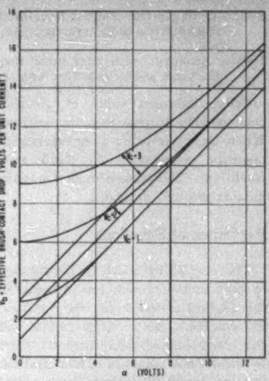

Fig. 1. Effective brush-contact drop V_b versus reactance voltage

Straight lines: $V_b = V_c + \alpha$

Curves:

$$V_b = V_c + \left(\frac{\epsilon^{\alpha/V_c}+1}{\epsilon^{\alpha/V_c}-1}\right)\alpha$$

$$\alpha = n_0K_l{}^2E_rb$$

$$r_b' = V_B/E_1$$

With Initial Load

The derivation of the foregoing equations for effective brush resistance is based on the assumption that there is no flux in the commutating region up to peak armature current. Experimental data[4] show that if a machine is short-circuited with no initial load there is a negligible flux change. With initial load, however, the interpole flux is built up to a value dictated by the load so that the reactance voltage for the initial load is compensated. Thus, it appears that for any initial load there is no effective brush drop nor shift in the point of current commutation. In the case of a generator, only that part of peak current represented by the difference between the peak current and the initial current $i_a' - i_{a0}$ can give rise to an uncompensated reactance voltage and to a shift in the center of current commutation. Hence, if linear commutation is assumed over the entire brush face, then the reactance drop for i_a' is $n_0E_ri_a'$ for the condition of zero initial current and $n_0E_r(i_a' - i_{a0})$ for initial load i_{a0}. Similarly, if the effective brush shift is b commutator segments for i_a' when the initial load current is zero, then the brush shift is $1-(i_{a0}/i_a')\,b$ when the initial load current is i_{a0}. This formulation results because at i_{a0} the brush shift is zero. Therefore, the reactance voltage pu current at i_a' for a generator is

$$\alpha = b(1 - i_{a0}/i_a')n_0E_r(1 - i_{a0}/i_a')$$

In the case of a motor with initial load, the initial commutating flux is in the wrong direction to compensate any of the reactance voltage under short circuit. When a motor is subjected to short circuit, the armature current reverses; but, as in the case of a generator, the commutating flux remains practically unchanged in magnitude and direction up to peak short-circuit current. The magnitude of the reactance voltage at i_{a0}, which is compensated by the initial commutating flux, is $n_0E_ri_{a0}$. This is equal to the voltage generated in each armature coil by the commutating pole flux when the armature current reverses. This voltage effectively increases the reactance voltage that would exist if there were no initial commutating flux. The uncompensated reactance voltage for a motor with initial load i_{a0} is then $n_0E_r[1+(i_{a0}/i_a')]$ pu current, and the effective brush shift is $[1+(i_{a0}/i_a')]b$. Hence, for a motor the reactance voltage pu current at i_a' is

$$\alpha = b(1 + i_{a0}/i_a')n_0E_r(1 + i_{a0}/i_a')$$

This equation is similar to that for a generator with initial load. Define the factor in parenthesis as follows

$$K_l = (1 \pm i_{a0}/i_a') \qquad (7)$$

where the plus sign applies for a motor with initial load and the negative sign applies for a generator with initial load. Then α at i_a' for operation as a motor or as a generator and for any i_{a0} and n_0 is

$$\alpha = n_0K_l{}^2E_rb \qquad (8)$$

and equation 6 for effective brush-contact resistance r_b' is always applicable when values of K_l as defined by equation 7 are used. In determining values for the load factor K_l, it is recommended that an estimate of i_a' equal to 10 e_0 be used. This estimate is not critical and will have negligible effect on the final computed value of i_a'.

Total Demagnetization Factor r_x'

The demagnetization of the main field, or the reduction in the air-gap flux can be attributed to three distinct effects resulting from short circuit:

1. Direct-axis armature demagnetization, which is proportional to the effective brush shift and the magnitude of armature current.

2. The series field which magnetizes or demagnetizes the main field depending on the direction of series field ampere-turns during short circuit.

3. Armature crossmagnetization, which effectively decreases the permeance of the air gap.

The constant K_s' used represents the direct-axis armature-demagnetizing mmf pu current per pole at peak armature current. As in steady state, this quantity is proportional to twice the angle of brush shift. Hence, for an effective brush shift equal to $b/2$ commutator segments

$$K_s' = bPm_{a1}/B \tag{9}$$

for the condition of no initial load. Under initial load conditions it has been shown that b becomes K_lb. Hence, under the condition of initial load

$$K_s' = K_lbPm_{a1}/B \tag{10}$$

For simplicity, the derivation for r_z' is for the case of a differentially connected generator with initial load. For other initial conditions such as operation as a motor or cumulative connection of the series field, the derivation would be parallel to that illustrated. The equation for the flux ϕ_d' at time of peak armature current in terms of the direct-axis mmf and the effective air-gap permeance p' for the case considered is

$$\phi_d' = [i_f' - m_{s1}i_a' - K_s'(i_a' - i_{a0})]p' \tag{11}$$

It is shown in Appendix I that by applying the theorem of constant flux linkages to the shunt field of a differentially connected generator the following equation results

$$\phi_0 + n_f(i_{f0} - K_{fs}m_{s1}i_{a0}) = \phi_d' + n_f(i_f' - K_{fs}m_{s1}i_a') \tag{12}$$

The determination of K_{fs} and applicable values are given in Appendix II. Solving equation 12 for i_f' gives the following expression

$$i_f' = (\phi_0 - \phi_d')/n_f + i_{f0} + K_lK_{fs}m_{s1}i_a' \tag{13}$$

Here, $\phi_0 - \phi_d'$ represents the loss in useful air-gap flux at peak armature current. The corresponding loss in voltage e_z' equals $n_0(\phi_0 - \phi_d')$, and from equation 2 the following may be written

$$\phi_0 - \phi_d' = r_z'i_a/n_0$$

Substituting this relation in equation 13, the value of shunt-field current at peak armature current is

$$i_f' = (r_z'i_a')/n_0n_f + i_{f0} + K_lK_{fs}m_{s1}i_a' \tag{14}$$

By the simultaneous solution of equations 11 and 14, i_f' is eliminated and the following equation is obtained

$$(r_z'i_a')/n_0n_f - \phi_d'/p' = K_s' + (1 - K_{fs}) \times (i_a' - i_a) - (i_{f0} - m_{s1}i_{a0}) \tag{15}$$

The initial direct-axis mmf $(i_{f0} - m_{s1}i_{a0})$ in equation 15, by using assumptions 3 and 4, can be written as follows

$$i_{f0} - m_{s1}i_{a0} = \phi_0/p_0 \tag{16}$$

Then substituting this relation and the following expressions for ϕ_0 and ϕ_d' in equation 15

$$\phi_0 = e_0/n_0 = i_a'(r' + r_z')/n_0$$

$$\phi_d' = (e_0 - r_z'i_a')/n_0 = i_a'r'/n_0$$

r_z' may be solved for, giving

$$r_z' = \frac{n_f}{1 + (n_f)/p_0} \{n_0K_l[K_s' + (1 - K_{fs})m_{s1}] + [(1/p') - (1/p_0)]r'\} \tag{17}$$

At no load, base speed and base voltage p_0 is equal to unity; in normal operation it will not differ appreciably from this value. The expression $(1/p') - (1/p_0)$ represents the change in reluctance of the air gap. When a machine is fully compensated, the value of this expression becomes negligible and may be assumed equal to zero. In the computation of r_z' which is usually not more than 30 per cent of the total resistance, r_d' it is sufficiently accurate to estimate i_a' by e_0/r' in the expression for p'. The derivation of r_z' and i_f' has been given for a differentially connected generator. The derivations for a cumulatively connected generator and for initial operation as a motor, either cumulative or differential, are similar. The equations of r_z' and i_f' for all these possible conditions of initial operation are expressed in concise form by the equations in the section entitled "Summary."

EQUATIONS FOR TRANSIENT CURRENT

The philosophy leading to current-time plots of short-circuit transients of a d-c machine is that of imposing specific boundary restrictions on the peak magnitude, rise, decrement, and steady-state magnitude of the current. These conditions are introduced into equation 18 which is the simplest form of a solution of an inductively coupled 2-loop system. That is

$$i = c_1e^{-\gamma t} + c_2e^{-\beta t} + c_3 \tag{18}$$

where

c_3 = steady-state current
$c_1 + c_2 + c_3$ = initial current
$\gamma = 1/T_r$, rise factor
$\beta = 1/T_d$, decrement factor

The peak current i_a' and i_f' are obtained by equations 4 and 34. After computation of the time constants T_r and T_d, the constants c_1 and c_2 may be determined through cut-and-try numerical reiterations until the peak armature current given by equation 18 is in agreement with the value obtained under short-circuit calculations. Simultation of equation 18 by an analogue computer will expedite these computations and display the current-time plot of the shunt-field and armature circuits. From equation 18 the time to peak is given by

$$t_{pa} = 1/(\gamma - \beta) \ln(-\gamma c_1/\beta c_2) \tag{19}$$

The initial rate of rise is given by differentiation of equation 18 and setting t equal to zero

$$di/dt = -\gamma c_1 - \beta c_2 \tag{20}$$

The factors γ and β which appear in equation 18 may be approximated by the reciprocal of the armature and shunt-field circuit time constants T_a and T_f respectively. However, a more accurate estimate of these factors can be made if the coefficient of mutual induction is introduced. In a linear inductively coupled 2-loop system, the defining equation for the time constant is

$$\tau = \frac{(\tau_a + \tau_f) \pm [(\tau_a + \tau_f)^2 - 4n\tau_a\tau_f)]^{1/2}}{2} \text{ seconds} \tag{21}$$

where

$$n = 1 - K^2 \tag{22}$$

Coefficient of leakage between two circuits of time constants τ_a and τ_f, with

$$K = M_{f-a}/(L_aL_f)^{1/2}$$

Coefficient of coupling between the shunt-field and armature circuits, with

$$M_{f-a} = PN_f\phi_{f-a}10^{-8}/I_{a1} \text{ henrys} \tag{23}$$

$$\phi_{f-a} = (K_s'K_l \pm m_{s1})(\Delta p)\phi_1 \text{ maxwells per pole per base current} \tag{24}$$

In equation 24 the plus and minus sign is used for differential and cumulative action of the series field respectively. Equation 21 provides T_r and T_d for the specific terms employed and applicable times.

It can be assumed with satisfactory accuracy that the decrement of both armature and shunt-field currents is dependent on the shunt-field inductance, while the rise time to peak is essentially a function of the armature-circuit inductance. However, the coefficients of self and mutual induction change during the short circuit because of saturation, eddy-current effects, and commutation. To effect a simple solution while taking into account as much of the actual phenomena as possible, the following procedure is used. This method restricts itself to those factors which can be obtained at various stages in a short-circuit calculation.

RISE FACTOR

Computation of the rise factor requires the time constants τ_a, τ_f and the leakage coefficient n, which exist immediately after short circuit. These initial values are determined from the following equations

$$\tau_a = T_a = L_d/r'R_1 \text{ seconds} \tag{25}$$

$$\tau_f = T_f = L_f/R_f \text{ seconds} \tag{26}$$

$$M_{f-a} = PN_f(K_3'K_1 \pm m_{s1})(\Delta p)_0\phi_1 10^{-8}/I_{a1} \text{ henrys} \tag{27}$$

In general, calculations of both armature and shunt-field inductances are for the unsaturated condition. Initial conditions of load and field excitation will often contribute to a sufficient change in saturation to make the unsaturated values inapplicable. The effects of a variable degree of saturation are difficult to calculate for the armature circuit because it is composed of the armature, compensating, series, and interpole windings. Some of these windings are in opposition so that only the respective leakage linkages contribute to the net inductance. A method for calculating the unsaturated armature-circuit inductance is shown in reference 8. Any changes in initial saturation may be taken into account for L_f and M_{f-a}, as shown in Appendix III. A solution of equation 21 for the smaller of the two roots will provide T_r when the values of T_a, T_f and n are substituted.

Therefore

$$\gamma = \frac{2}{(T_a + T_f) - [(T_a + T_f)^2 - 4nT_aT_f]^{1/2}} \tag{28}$$

with

$$n = 1 - (M_{f-a})^2/L_dL_f$$

DECREMENT FACTOR

The computation of the decrement factor is similar to that for the rise factor. In this case, the constants τ_a, τ_f, and n, which exist at the peak current, are used. Calculation of these constants, as outlined by the following equations, requires a knowledge of shunt-field and armature-circuit inductances, the respective circuit resistance, and mutual inductance at peak current

$$\tau_a = T_a' = L_d/r_d'R_1 \tag{29}$$

$$\tau_f = T_f' = L_f'/R_f \tag{30}$$

Fig. 2. Block diagram for an analogue computer system

$$M_{f-a}' = PN_f(K_3'K_1 \pm m_{s1})\Delta p'\phi_1 10^{-8}/I_{p1} \text{ henrys} \tag{31}$$

In previous work,[5] the time constant of the armature circuit has been reduced by factors of two or three. This is rather severe, because the region of saturation in the armature circuit is small and the leakage inductances caused by the air paths predominate. As stated previously, the effects of saturation upon armature-circuit inductance are difficult to evaluate. A small reduction in the armature-circuit time constant is shown in equation 29, which utilizes the effective transient resistance In Appendix III a development is shown for calculating L_f' and M_{f-a}' at peak time A solution of equation 21 for the larger of the two roots will provide T_d when the values of T_a', T_f', and n' are substituted

Therefore

$$\beta = \frac{2}{(T_a' + T_f') + [(T_a' + T_f')^2 - 4n'T_a'T_f']^{1/2}} \tag{32}$$

with

$$n' = 1 - (M_{f-a}')^2/L_d'L_f'$$

ANALOGUE COMPUTER SOLUTION AND DISPLAY

A block diagram illustrating simulation of equation 18 on an analogue computer is shown in Fig. 2. Adjustment of coefficient boxes c_1, c_2, and c_3 is made until the conditions of initial, peak, and steady-state armature current are satisfied. From the displayed trace, the armature peak time can be obtained. In an actual short circuit, it is often difficult to ascertain accurately when the armature current peaks. It is easier to determine the time it takes the current to reach a specific percentage of the maximum and the time that elapsed before the current decays below this same percentage. These data would be of more value than the peak current and the time to peak.

To plot the shunt field current the value of armature peak time is obtained from the displayed trace or from equation 19. This peak time and the value of shunt-field current I_f' are imposed as constraints on equation 18, employing the same rise and decrement factors as those for the armature. Adjustment of coefficient boxes c_1 and c_2, which are equal to each other for the separately excited machines, is made until the foregoing boundary restrictions for the shunt-field current are contained in a transient trace.

Limitations

The equations developed for short-circuit calculations are necessarily limited in their application by the simplifying assumptions made in their derivation. In general, the assumption of constant speed is satisfactory since the time to peak armature current is small and, for large machines, the inertia of the armature is great enough to maintain the speed substantially constant up to this time. This assumption does result in higher values of calculated peak current than if the actual speed were used.

TOTAL DEMAGNETIZATION FACTOR

The assumption that the effective permeance of the air gap at peak armature current is only affected by saturation of the armature teeth caused by armature crossmagnetization is not valid under all operating conditions. At low initial flux density and low short circuit, the teeth which carry effective flux ϕ_d' may not be at intrinsic saturation. At high initial flux density and high short-circuit current not only the teeth which carry the effective flux ϕ_d' are at intrinsic saturation but also the iron below these teeth. In the latter case, the present formulation for r_z' will give a value for this quantity which is low and will result in a calculated value of I_a' which is too high. Hence, for initial voltages greater than 1 pu, it is probable that the iron below the teeth reaches intrinsic saturation and a correction in p', the effective permeance at peak current, should be made to reflect this condition. This correction on p' would result in a lower value for this quantity than is now obtained. If, however, such a correction is not made, the results will be on the safe side in that the calculated value of armature current will be high.

THEOREM OF CONSTANT FLUX LINKAGES

The assumption that the theorem of constant flux linkages can be applied to the shunt-field circuit is only valid if the resistance of this circuit is very small or if the time to peak current is small. Its use is justified on the basis that the time to peak current is small, and that the actual resistance of the shunt-field results in the loss of negligible linkages in the short time considered. The actual loss in linkages would result in lower values of peak current than the calculated values.

BRUSH-CONTACT RESISTANCE AND ARMATURE-DEMAGNETIZATION FACTOR

For the condition of zero initial load, the expression used for r_b' and K_3' are the same as those derived by Linville.[2,3] They have, however, been modified to account for the effects of initial load. Both the original derivations for r_b' and K_3' and their modifications for initial load conditions are based on simplifying assumptions that give an approximate solution. The assumption that there is on change in commutating flux up to peak current is approximately true for solid interpoles. With laminated interpoles,[4] this assumption would not be true and r_b' as now obtained should be reduced. The assumption that the center of current commutation is at the trailing brush edge at peak armature current may be justified qualitatively since it is known that undercommutation shifts the center of current commutation in the direction of the trailing brush edge. The assumption that it is exactly at the trailing brush edge at peak armature current for the condition of no initial load is justified on the basis of simplicity rather than rigor.

Linville[3] in his derivation of an expression for r_b' obtains an equation for the current density in the brush face at peak armature current. Although this current distribution is exponential in form, it is always positive and is independent of the magnitude of peak armature current. Experimentally, however, it is found that the current distribution in the brush face is a function of the magnitude of peak armature current and, at one edge of a brush may be zero or even negative.

The rigorous development of expressions for commutation losses, eddy-current, and demagnetization effects under short-circuit conditions would prove extremely difficult, it not impossible, and would lead to complicated and unwieldy expressions. For this reason, it is felt that a less rigorous analysis having the advantage of simplicity and reflecting in an admittedly approximate fashion the physical changes that occur will prove sufficiently accurate for useful engineering results.

TRANSIENT CURRENTS

In a previous paper[3] the assumption has been made that the shunt-field and armature-circuit currents peaked at the same time. This is an unnecessary restriction. As a matter of fact, the field current peaks before the armature current. The present development thus more accurately reflects the actual situation.

This method utilizes an analogue computer to enforce the computed boundary conditions for the armature- and shunt-field circuit currents and enables a rapid solution for the constants in a simple equation. A single current-time trace is obtained, uniquely fulfilling the foregoing limitations without resorting to changes in constants, curve shifting, or other manipulations mid-way in the time plot. The time to reach peak current is very indefinite in those cases where the peak current is maintained substantially constant for a relatively long time. In view of this, the time to reach 90 per-cent of the peak value and elapsed time when the current is above 90 per-cent of its maximum would be definite and useful information.

Summary of Equations

EQUATIONS FOR PEAK ARMATURE CURRENT

The equations for peak armature current are as follows

$$i_a'=e_0/r_d' \tag{4}$$

where

$$r_d'=r_s+r_w+r_b'+r_z'$$

$$r_b'=\alpha/E_1\left(\frac{e^{\alpha/V_c}+1}{e^{\alpha/V_c}-1}\right)+V_c/E_1 \tag{6}$$

$$\alpha=n_0K_1^2E_rb$$

$$r_z'=\frac{n_f}{1+n_f/p_0}\{n_0K_1[K_3'\pm(1-K_{f3})m_{s1}]+[(1/p')-(1/p_0)]r'\} \tag{33}$$

where $(1/p')-(1/p_0)$ is considered zero for a fully compensated machine. The field current I_f' existing at peak armature current is obtained from the equation

$$i_f'=i_{f0}+[(r_z'/n_0n_f)\pm K_1K_{f3}m_{s1}]i_a' \tag{34}$$

Machines under short circuit operate as generators and the action of the series field under short circuit determines the sign to be used in equations 33 and 34. If the series field, when the machine is under short circuit, aids the shunt field (cumulative connection), the minus sign should be used; whereas if it opposes the shunt field (differential connection), the plus sign should be used. It will be understood that, if a machine is operated as a cumulatively compounded motor before short circuit, during short circuit the machine will operate as a differentially compounded generator, and it is the operation under short circuit that determines the sign to be used in equations 33 and 34.

EQUATIONS FOR TRANSIENT CURRENT

The armature current is given by the following equation

$$i=c_1e^{-\gamma t}+c_2e^{-\beta t}+i_s \tag{35}$$

where

$$i_s=\frac{i_{f0}}{(r/pn_0)+K_1K_3+m_{s1}}$$

$$\gamma=\frac{2}{(T_a+T_f)-[(T_a+T_f)^2-4nT_aT_f]^{1/2}} \tag{28}$$

with

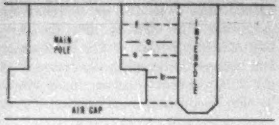

Fig. 3. Relation of shunt- and series-field windings to magnetic pole pieces

$n = 1-(M_{f-a})^2/L_dL_f$

$$\beta = \frac{2}{(T_a'+T_f')+[(T_a'+T_a')^2-4nT_a'T_f']^{1/2}} \qquad (32)$$

with

$n' = 1-(M_{f-a}')^2/L_d'L_f'$

Constants c_1 and c_2 in equation 35 are adjusted until the peak armature current i_a' is attained with the restriction that

$i = i_{a0}$ at $t = 0$

The armature current has a peak time given by

$$t_{pa} = [1/(\gamma-\beta)] \ln(-\gamma c_1/\beta c_2) \qquad (19)$$

The shunt-field circuit current is given by the following equation

$$i = c_1\epsilon^{-\gamma t}+c_2\epsilon^{-\beta t}+i_{f0} \qquad (36)$$

where for a separately excited machine, c_2 is equal to $-c_1$ and

$c_1 = (i_f'-i_{f0})/(\epsilon^{-\gamma t_{pa}}-\epsilon^{-\beta t_{pa}})$

For a self-excited machine, the constants c_1 and c_2 in equation 36 are adjusted until the current i_f' is reached at time t with the restriction that $i = i_{f0}$ at t equals zero, and $i = 0$ as t approaches infinity.

After obtaining the solution for the constants c_1 and c_2 in equation 35, the initial rate of rise of the armature current is given by

$di/dt = -c_1\gamma - c_2\beta$

In reference 14 it is shown how these equations are employed on five machines and results are compared with test data.

Appendix I. Derivation of Shunt-Field Flux Linkage Equations

For simplicity this derivation is based upon a differentially connected generator. The following assumptions are made: 1. The field windings have no partial linkages; and 2. initial armature current up to 1 pu does not effect the air gap by cross magnetization.

Initial Linkages

Initial conditions: $I_{a0} \leq 1$ pu; I_{f0}. The brushes are on neutral and there is no direct-axis armature mmf. Equation 37 expresses the flux linkages for the paths outlined in Fig. 3, where f and s represent the position of the shunt and series field windings respectively

$$\psi_0 = N_f(\phi_a+\phi_b+\phi_0) \qquad (37)$$

In terms of the path permeances, equation 37 becomes

$$\psi_0 = N_f^2I_{f0}(P_a+P_b+P_0)-N_fN_sI_{a0}(P_b+P_0) \qquad (38)$$

Equation 38 may be rewritten

$$\psi_0 = P_0N_fM_{f0}(1+n_{f0})-M_{s0}(1+n_{fs0}) \qquad (39)$$

where

$n_{f0} = N_fM_{f0}(P_a+P_b)/N_fM_{f0}P_0 = (P_a+P_b)/R_0$

$n_{fs0} = N_fM_{fs0}P_b/N_fM_{fs0}P_0 = (P_b/P_0)$

Divide equation 39 by N_f and rewrite to form

$$\psi_0/N_1 = \phi_0+P_0n_{f0}(M_{f0}-K_{fs0}M_{s0}) \qquad (40)$$

where

$K_{fs0} = n_{fs0}/n_{f0} = P_b/(P_a+P_b)$

Define

$n_f = N_fM_{f1}(P_a+P_b)/N_fM_{f1}P_1 = (P_a+P_b)/P_1$

$n_{fs} = N_fM_sP_b/N_fM_sP_1 = P_b/P_1$

Then it follows that

$K_{fs} = n_{fs}/n_f = P_b/(P_a+P_b) = K_{fs0}$

and

$n_{f0}/n_f = P_1/P_0$

Equation 40 can now be written as

$$\psi_0/N_f = \phi_0+P_1n_f(M_{f0}-K_{fs}M_{s0}) \qquad (41)$$

where calculation of K_{fs}, which is a function of position of the series field, is shown in Appendix II.

Equation 41 may be expressed with pu quantities by

$$\psi_0 = \phi_0+n_f(i_{f0}-K_{fs}m_{s1}i_{a0}) \qquad (42)$$

LINKAGES AT PEAK ARMATURE CURRENT

Peak time conditions: i_a' and i_f'. The flux linkages at peak are given by equation 43 for the paths outlined in Fig. 3

$$\psi' = N_f(\phi_a'+\phi_b'+\phi_d') \qquad (43)$$

In terms of the path permeances, equation 43 becomes

$$\psi' = N_fM_f'(P_a'+P_b'+P') = N_fI_a'(P_b'N_s+P'N_s+P'N_a') \qquad (44)$$

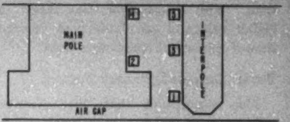

Fig. 4. Positions corresponding to actual and effective series-field windings

Equation 44 may be rewritten as

$$\psi' = N_f'P'M_f'(1+n_f')-N_sI_a'(1+n_{fs}')+N_a'I_a' \qquad (45)$$

where analogous to the previous development

$n_f' = (P_a'+P_b')/P' = (P_a+P_b)/P' = n_fP_1/P'$

$n_{fs}' = P_b'/P' = P_b/P' = n_{fs}P_1/P'$

as the permeance of the air paths a and b are not greatly influenced by peak currents.

Equation 45 may now be written as

$$\psi' = N_f[(M_f'-M_s'-N_a'I_a')P'+n_fP_1(M_f'-K_{fs}M_s')] \qquad (46)$$

Equation 46 may be expressed with pu quantities by

$$\psi' = (i_f'-m_{s1}i_a'-K_s'K_li_a')p'+n_f(i_f'-K_{fs}m_{s1}i_a') \qquad (47)$$

where further simplification employing equation 11 leads to

$$\psi' = \phi_d'+n_f(i_f'-K_{fs}m_{s1}i_a') \qquad (48)$$

Application of the constant flux linkage theorem is expressed by equating equation 42 to equation 48 which results in

$$\phi_0+n_f(i_{f0}-K_{fs}m_{s1}i_{a0}) = \phi_d'+n_f(i_f'-K_{fs}m_{s1}i_a') \qquad (12)$$

Appendix II. Calculation of Leakage-Linkage Ratio K_{fs}

Development of Equations

Usually the series field is located at either one of two positions with respect to the shunt field; these are numbered 2 and 4, as shown in Fig. 4. Without an actual series-field winding, an effective series field may result by a suitable arrangement of the connections between interpole and pole-face windings. In Fig. 4, the boxes labeled 1, 3, and 5 show the origin of those paths and their relative positions in passing around the main pole.

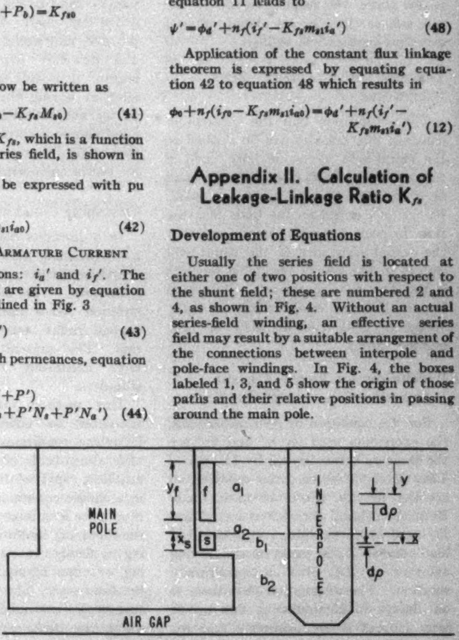

Fig. 5. Detail for development of partial flux linkage equations

By extension of the development in Appendix I to the case of partial linkages, a more accurate equation for the computation of K_{fs} should result. The following development utilizing partial linkages is offered for position 2, as shown in Fig. 5, with a differential series-field connection.

For path a_1 as a function of distance y, the turns n equal N_f/y_f, the mmf M_f equals $(M_{f1}/y_f)y$, and the permeance P equals $(P_{a1}/y_f)y$.

For the tube dP at distance y there is a

$$d\phi_{a1}=M_f dP=(M_{f1}/y_f)(P_{a1}/y_f)y\,dy$$

The partial leakage linkages $N_f\phi_{a1}$ caused by the shunt-field mmf alone are given by

$$\int_0^{y_f} n\,d\phi_{a1}=N_f M_{f1}P_{a1}/3 \qquad (49)$$

For path a_2, the entire mmf M_{f1} acts on permeance Pa_2, creating flux ϕ_{a2} linking all turns N_f

$$N_f\phi_{a2}=N_f M_{f1}P_{a2} \qquad (50)$$

For path b_1, as a function of distance x, all the turns N_f are linked, the mmf M equals $M_{f1}-(M_s/x_s)x$, and the permeance P equals $(P_{b1}/x_s)x$.

For the tube dP at distance x there is a

$$d\phi_{b1}=m\,dP=\left(M_{f1}-\frac{M_s}{x_s}x\right)\frac{P_{b1}}{x_s}dx$$

The partial linkages $N_f\phi_{b1}$ caused by the combination of shunt- and series-field mmf are given by

$$\int_0^{x_s} N_f d\phi_{b1}=N_f(M_{f1}P_{b1}-M_aP_{b1}/2) \qquad (51)$$

For path b_2, the entire mmf $(M_{f1}-M_s)$ is acting on permeance Pb_2 creating flux ϕ_{b2} linking all turns N_f

$$N_f\phi_{b2}=N_f(M_{f1}-M_s)Pb_2 \qquad (52)$$

The total initial linkages for the shunt field are obtained by summing up equations 49 through 52 plus the initial air-gap linkages $N_f(M_{f1}-M_s)P_0$

$$\psi_0=N_fM_{f1}(P_{a1}/3+P_{a2}+P_{b1}+P_{b2}+P_0)-N_fM_s(P_{b1}/2+P_{b2}+P_0) \qquad (53)$$

In a similar manner to the case in Appendix I, equations 54 and 55 may be written by inspection

$$n_{f0}=(P_{a1}/3+P_{a2}+P_{b1}+P_{b2})/P_0 \qquad (54)$$

$$n_{fs0}=(P_{b1}/2+P_{b2})/P_0 \qquad (55)$$

Therefore

$$K_{fs}=(P_{b1}/2+P_{b2})/(P_{a1}/3+P_{a2}+P_{b1}+P_{b2}) \qquad (56)$$

Generalized Values

Instead of attempting a calculation for the individual leakage-linkage coefficients, an estimate of their ratio K_{fs} is possible. Average values of K_{fs}, in general, are applicable for the numbered positions shown in Fig. 4.

The following magnitudes of K_{fs} are suitable:

Position	1	2	3	4	5
K_{fs}	0.10	0.65	0.80	0.95	0.85

Calculation of Individual Permeances

To compute the permeances of the flux paths outlined in Fig. 5, the usual assumption of infinite permeability of the iron is made so that only the air-path permeance is effective with

$$\mathcal{P}=\mu A/l$$

If it is desirable to obtain an estimate of the absolute value of n_f or n_{fs}, the value of P_1 is needed. This base permeance can be obtained in either of two ways. If a saturation curve is available, this permeance of the air gap corresponding to one pole is

$$P_1=\frac{\phi_1 10^{-8}}{M_{f1}}$$

Without a no-load saturation curve, the permeance of the air-gap line may be approximated by

$$P_g=\frac{4\pi p_a l_a 10^{-7}}{39.3gF} \qquad (57)$$

Then

$$P_1=\frac{P_g}{K_t} \qquad (58)$$

Appendix III. Calculation of Initial and Peak Time Shunt-Field Inductance

Initial Inductance

In the computation of shunt-field inductance it is possible to factor in the changes in saturation. If a no-load saturation curve is available, the calculation of the shunt-field winding inductance caused by direct-axis flux linkages is at 1 pu excitation

$$L_{g1}/\text{pole}=N_fE_1\Delta p_1/cN_1I_{f1}\text{ henrys} \qquad (59)$$

where

$$c=PZ/a60$$

$\Delta p_1=de/n_s d(i_f)$ pu, and at i_f equal to I_{f1}

In addition to the contributions of air-gap flux, there is leakage self-inductance as a result of shunt-field leakage linkages. Since it has been shown in Appendix I that these linkages are proportional to the shunt-field mmf

$$L_l/\text{pole}=n_fN_fE_1p_1/cN_1I_{f1} \qquad (60)$$

where

$p_1=e/n_si_f$ pu $=1$ at i_f equal to I_{f1}

The total initial shunt-field inductance L_f per pole is given by the sum of equations 59 and 60. If there is an initial load, the shunt-field inductance caused by the air gap can be modified. It has been found that the incremental permeance Δp (proportional to the slope of the no-load saturation curve) can be related to the permeance p (proportional to e/i_f) approximately by a cube law. The incremental permeance for the general case is

$$\Delta p_0=\Delta p_1(p_0)^3\text{ pu} \qquad (61)$$

The total initial shunt-field inductance for the general case is

$$L_f=[(p_0)^3L_{g1}/\text{pole}+L_l/\text{pole}]P \qquad (62)$$

If a no-load saturation curve is not available, then Δp_1 in equation 59 may be estimated at base speed by

$$\Delta p_1=(1/K_t)^3\text{ pu}$$

The value of Δp_0 obtained from equation 61 is also employed in determining coefficient M_{f-a} given in equation 27.

Inductance at Peak Time

In the computations of shunt-field inductance, it is possible, as before, to factor in the changes in saturation; those evidenced at peak time. The incremental permeance $\Delta p'$ is related to the permeance p' by a cube law

$$\Delta p'=\Delta p_1(p')^3\text{ pu} \qquad (63)$$

It follows that the total shunt-field inductance at peak is

$$L_f'=[(p')^3L_{g1}/\text{pole}+L_l/\text{pole}]P \qquad (64)$$

The value of $\Delta p'$ obtained from equation 63 is also employed in determining M_{f-a}' given by equation 31.

D-C Machines—Short-Circuit Calculations and Test Results

J. P. O'CONNOR
MEMBER AIEE

J. CYBULSKI
ASSOCIATE MEMBER AIEE

THE wide use of d-c machinery in naval and industrial applications and the demand for reliability under all conditions of operation increases the importance of the design and operation of protective equipment. For this reason the need for a reliable method to compute the transient currents of motors and generators when a system is subjected to a fault is obvious.

The field of rotating d-c machinery includes a very wide variety of types and designs. The equations used in this paper, however, are applicable, for the calculation of fault transients, to all machines used for power applications in industry and in the U. S. Navy.

A description of the theory and the derivation of equations used in this paper have been given in a companion paper.[1] Like other equations given in the literature[2] for the computation of peak short-circuit current, the equations used here are based upon simplifying assumptions. Hence, a discrepancy between calculated and test values is expected. For this reason the accuracy of results obtained by computation is unknown unless test results are available. If test results were available on a large group of machines for comparison with computed results, a degree of confidence could be established in the validity of equations for the computation of peak short circuit of any machine in the normal power range. Reported test results in the literature, however, especially for machines of 1,000 kw and larger, are extremely meager. Confidence in the reliability of any method for the computation of short-circuit current can only be established by the confirming evidence of test results.

Test Values and Computed Results

In this paper the test results on five machines, which were part of a mock submarine propulsion plant, have been used to indicate the accuracy of computations. In a previous paper[3] test results on four of the five machines reported on here were given and were compared with the computed results obtained by the best method[3] then available.

The name-plate data of the five machines used for short-circuit tests are given in Table I, and the basic constants required for short-circuit calculations are given in Table II. A comparison of test peak short-circuit currents and the values obtained by computations are shown in Table III. A comparison of calculated and test transient currents appears in Figs. 1 through 6 inclusive.

Nomenclature

Upper-case letters denote total quantities. Exception is made for flux and flux linkages where the same size letter is used. Lower-case letters denote per-unit (pu) quantities; total quantities divided by their respective base values result in a pu system.

A = effective area of armature conductors in each slot, square inches; a_1h

a_1 = width of space taken by copper conductors in slot, inches (average $a_1 = 0.78b_1$)

b_1 = width of armature slot, inches (average $b_1 = 0.37p_a/n_1$)

C_s = number of armature conductors per slot, Z/S

d_a = diameter of armature, inches

E_0 = armature generated voltage, before short circuit, volts; $V_t \pm R_a I_{a0} \pm V_c$ (plus and minus signs are taken for generators and motors respectively)

E_1 = voltage generated at base flux, base speed, and no load, volts

f = frequency of commutation, cycles per second; $PN_1/120$

h = height of space taken by copper conductors in slot, inches (average $h = 0.87d_s$; if d_s, a_1, and b_1 are not known use average $h = 3.46ZI_c/\pi d_a j$)

i_a'' = estimate of steady-state armature circuit current, pu

I_c = armature conductor current, amperes; I_{a1}/a

I_{a1} = rated armature current at which the reactance voltage has been determined

I_{f1} = shunt field current corresponding to base field magnetomotive force, M_{f1}/N_f

i = instantaneous current, either armature or shunt field; units are in amperes or pu, depending on the context in which they are used

j = current density in armature conductors, amperes per square inch; $C_s I_c/A$; generalized value 2,500

K_l = initial load coefficient, $1 \pm (i_{a0}/10e_0)$; plus and minus sign for initial motor and generator action respectively

K_s = steady-state load coefficient, $1-(1/3e_0)$

K_2 = permeance constant of the "space flux," pu; generalized value 0.14

L_d = initial armature circuit inductance, henrys

N_a = armature winding turns per pole, $Z/2a$

N_b = pole-face winding turns per pole

N_f = shunt field winding turns per pole

N_1 = speed at which the reactance voltage has been determined, rpm

p = steady-state permeance, pu; $(K_1/i_a''+K_2)$, $p \leq K_l$

p_1 = permeance at base conditions in per unit equals one

R_a = resistance of armature winding only, ohms

R_1 = base resistance, ohms; E_1/I_{a1}

r_b' = effective brush-contact resistance at peak short-circuit current, pu

$r_x' = r_{xd}' + r_{xq}'$, an equivalent resistance to account for the loss in air-gap flux at peak armature current, pu

Table I. Name-plate Data on Five Machines

Machine	Kw	RPM	Horse-power	Constant Speed Rise, Degrees Centigrade	Volts	Amperes	Duty	Ventilation

Paper 55-114, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 22, 1954; made available for printing December 16, 1954.

J. P. O'CONNOR and J. CYBULSKI are with the Naval Research Laboratory, Washington, D. C.

r_{xd}' = component of r_x' due to direct demagnetization

r_{xq}' = component of r_x' due to crossmagnetization

S = number of armature slots, p_pPn_t/p_a

t_{pa} = time to peak armature current, seconds; equation 19 of reference 1

t_{pf} = time to peak field current, seconds; equation 8 or 10

V_{f0} = initial voltage across shunt field circuit, volts

V_t = terminal voltage of machine, volts

V_a' = effective increase in armature winding resistance drop at base speed and current

ϕ_i = iron flux for intrinsic saturation, pu; generalized value 1.1

ϕ_1 = air-gap flux per pole corresponding to base field magnetomotive force at no load, maxwells

SUBSCRIPTS

b = effective brush contact

d = total armature circuit

e = external to machine winding including the short circuit

f = shunt field circuit

0 = initial conditions

s = series field winding

w = armature winding and all other machine windings in series

x = loss of air-gap flux resulting direct magnetization plus crossmagnetization

1 = base quantity; with magnetomotive forces other than M_{f1} taken at base armature current

Prime indicates the value of the

quantity corresponding to peak armature current. Double prime indicates an estimate. Where there is no subscript or superscript, the quantity corresponds to a steady-state condition. Exception is made for initial inductances and mutual inductances.

Additional symbols are defined in Tables II and IV and in reference 1.

Equations for Short-Circuit Calculations

The equations employed for short-circuit calculations have been derived in a companion paper[1] and are listed there. The peak armature current under short-circuit conditions is

$$i_a'=e_0/r_d' \qquad (1)$$

where

$$r_d'=r'+r_z'=r_e+r_w+r_b'+r_z' \qquad (2)$$

An improvement in an estimation of i_a' results when the equation for r_z', equation 33 of reference 1, is separated as follows

$$r_z'=r_{zd}'+r_{zq}' \qquad (3)$$

Then

$$r_{zd}'=\frac{n_f n_0 K_I}{1+n_f}\left[K_3'\pm(1-K_{fs})m_{s1}\right] \qquad (4)$$

$$r_{zq}'=\frac{n_f}{1+n_f}\left(\frac{1}{p'}-1\right)r' \qquad (5)$$

where the plus or minus sign in equation 4 is used when the series field opposes or aids the shunt field respectively during a short circuit. In a fully compensated machine there is no crossmagnetization and therefore the term r_{zq}' is equal to zero. Hence for a fully compensated machine the peak armature current is

$$i_a'=e_0/(r'+r_{zd}') \qquad (6)$$

When a machine is not fully compensated, or without compensation, it is first handled in the same way as a fully compensated machine. The value of the peak armature current thus obtained is a first approximation and is too high, since r_{zq}' was assumed equal to zero. This first approximation of i_a' is then used to compute r_{zq}'. If the computation of r_{zq}' results in a negative value, r_{zq}' should be assumed equal to zero and equation 6 would apply. This procedure for machines that are not fully compensated is necessary because the peak permeance p' is defined in terms of the peak armature current i_a' in the form of

$$p'=K_1/i_a'+K_2 \qquad (7)$$

Hence to determine p' and r_{zq}' a good approximation to the peak current such as given by equation 6 is employed.

From the equations listed in the companion paper,[1] the following equations applicable to the shunt field have been derived:

For separate excitation

$$t_{pf}=\frac{1}{(\gamma-\beta)}\ln\gamma/\beta \qquad (8)$$

$$di/dt=-c_1(\gamma-\beta) \qquad (9)$$

For self-excitation

$$t_{pf}=\frac{1}{\gamma-\beta}\ln(-\gamma c_1/\beta c_2) \qquad (10)$$

$$di/dt=-(c_1\gamma+c_2\beta) \qquad (11)$$

Sample Calculation

The basic constants required for short-circuit calculations are described in Table II and values of these constants are also given for the five machines tested. From the basic constants, Table II, the derived or computed constants, Table V, are obtained. Table IV-A illustrates how the computed constants are obtained for machine G-2, and

Table IV-B shows in detail the computation of the peak short-circuit current and the corresponding shunt field current for the initial conditions given in Table III for run D-1. Table IV-C shows a detailed computation of the rise and decrement factors and steady-state short-circuit armature current for this run. From the results given in Tables IV-B and IV-C a complete transient solution can be obtained on an analogue computer.

A block diagram illustrating simulation by a *GAP/R* analogue computer is shown in Fig. 2 of reference 1. Before computation begins a calibration which involves scaling of time and magnitude is made for the coefficient boxes and the display cathode-ray tube. Actual times of interest of the order of 0.2 second are represented by a computing interval of 40 milliseconds. This electronic computation is repetitive, 20 times during a second, so that the solution may be displayed on a cathode-ray tube. With a rectangular co-ordinate grid on the cathode-ray tube the calibration is made so as to simplify the reading of the magnitude and time data. A picture is taken of the displayed transient and superimposed illuminated grid, thus giving a permanent record.

From the computer solution for run D-1, the coefficients of the equation for the transient, equation 35 of reference 1, are found for the armature current to be

$c_1=-6.30$, $c_2=4.46$, $c_3=1.76$ (calculated steady-state current)

The transient as obtained by the computer and the actual test transient are shown in Fig. 1. The computer curve was obtained by abstracting data every 0.01 second from a photograph of the trace. In Fig. 1 it will be observed that the computer curve is

smooth while the actual short-circuit trace shows the effect of severe arcing. The latter curve was obtained by taking the plotted points from an oscillogram and then drawing straight-line segments between the points to indicate the effect of arcing.

A similar abstraction of a computer solution for the shunt field current is shown in Fig. 2 together with the test data. The coefficient

$$c_1=-c_2=-2.2$$

was obtained for a separately excited field from the computer. It can also be calculated directly by evaluating equation 36 of reference 1 at the peak time for armature current.

The initial rate of rise and peak time for the armature and shunt field current may be obtained from the transient solution. However, it is preferable to utilize the coefficients c_1 and c_2 from the computer solution in the applicable equations. The initial rate of rise as calculated from these equations is shown in Table VI, as well as the peak current and time to peak.

In Figs. 3 and 4 comparisons are shown of the transient (test and computed) armature and shunt field currents respectively for machine M-2. A comparison of computed and test results on M-3 may be made in Figs. 5 and 6 for the armature and shunt field transient currents respectively.

If some of the design parameters in Table II are not available, then various approximations may be made for the resistance parameters, the peak current, and the initial rate of rise as shown in Appendix I.

Discussion of Results

Values of peak short-circuit armature current, as obtained from oscillograms and as computed, are given in Table III for 31 low-resistance short-circuit tests on five machines. A comparison of the

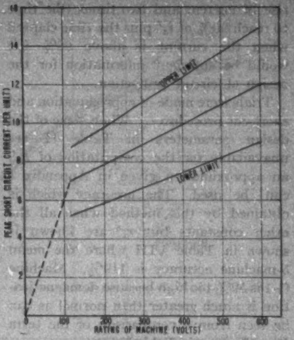
Fig. 8 (right). Peak zero resistance short-circuit current versus machine terminal voltage rating, rated conditions, no load initially



test and computed values of peak armature current for the various short-circuit runs on the machines used in this series of tests is indicative of the accuracy with which the peak short-circuit current can be computed for widely varying initial conditions of load, speed, and voltage. Over-all the calculated results obtained on the machines tested are good considering that each of these machines is of a special design for operation over a voltage range of 250 to 415 volts for shipboard service. The accuracy of the computations as shown in Tables III and VII would be better were it not for the occasional severe flashing which reduced the magnitude of the measured external current. Hence in those runs where flashing occurred the computed values are generally on the high side.

For those concerned with the design and application of protective equipment for d-c machinery, the peak short-circuit current at rated conditions and with no external resistance is considered most important. Computed and test values of peak short-circuit current for rated conditions and zero external resistance are given in Table VII. In this table the accuracy of the calculated data is given, using the test data that could be extrapolated to these conditions as a base. However, there was no test sufficiently close to full-load initial conditions for machines M-1 and M-2. For these machines a 1 pu change was employed as an estimate of the difference to be expected between the no-load to full-load test data. It is noted from Table VII that the higher currents occur for motor operation at no load and for generator operation at full load.

A graphical representation of the percent (%) accuracy obtained by computation of peak armature current is shown in Fig. 7. The abscissa in this figure represents the relative magnitude of calculated peak short-circuit current in % where the base value of peak current is that computed for rated conditions and no load. For a range of peak currents that vary in relative magnitude from 35% to 105%, the mean accuracy for all runs is 109% of the test values. If the runs where flashover occurred are excluded the mean accuracy for the remaining runs is 105%.

In some of the tests shown in Table III the transient field current was not recorded. In those cases where an oscillogram of the transient field current was taken the field current i_f' corresponding to peak armature was calculated, and is compared to the test peak field current in Table III. In the computation of the % accuracy of the field current, the test peak field current is taken as a base and the calculated field current i_f' is expressed as a percentage of the base. In general, the field current i_f' that exists at peak armature current is slightly smaller than the true peak field current because the field current peaks before the armature current. For this reason it was expected that the computed values of i_f' would be somewhat smaller than the test values of peak field current. An average accuracy of 93% was attained for the 17 runs available for comparison.

Although the computed transient curves compare favorably with the actual test data, the accuracy as to the time of the peak armature and field current is highly variable so that average figures cannot be cited. There are several reasons for errors in computed peak time. Primarily, the complex magnetic circuit with superimposed eddy-current effects cannot be simulated accurately with simple time constants. Even if more elaborate time constants are employed it remains difficult to evaluate correctly the effective inductance and resistance of the circuits at the various times. In addition, unpredictable flashing, interpole flux response, and steady-state current estimation contribute to errors in transient current plots. Therefore, instead of relying on an estimate of peak time from a current time plot, it is believed that the time interval when the computed current exceeds 90% or 95% of its peak value will, in general, include the actual test peak.

For example, in Fig. 1 a horizontal line has been drawn at the magnitude 95% of i_a', i.e.

$$0.95(5.29)=5.03 \text{ pu}$$

This line intersects the computed transient curve at two points: $t_{-0.95p}=0.019$ second and $t_{+0.95p}=0.044$ second. Those two times are indicative of the short-circuit behavior of the d-c machine. A different characteristic is illustrated in Fig. 3, where the percentage limits were dropped to 90% of i_a'. It is suggested that specifying the peak magnitude of current together with the initial rate of

Table IX. Initial Rate of Rise of Transient Currents

rise of current and two times (the time to reach 90% of i_a' plus the time elapsed when the current is above 90% i_a') would be sufficient information for the design of circuit protection.

Trials were made of approximation and short-cut procedures. When some of the design parameters in Table II are unavailable for the computation of r_x', an approximation given in Appendix I can be used. The accuracy which is obtained by this method when all the other constants but r_x' are known is shown in Table VIII where the mean 5-machine accuracy is 119%. Machine G-1 is 59% too high because demagnetization is much greater than normal as can be seen from a comparison of the term $(1-K_{fs})\,m_{s1}$ in Table V.

When the product $E_r b$ is not known an alternate procedure for computation of its value, developed in Appendix I, may be used. The accuracy obtained by this method when all the other constants are known is shown in Table VIII where the mean 5-machine accuracy is 95%.

A rough estimate of the peak armature current resulting from a short circuit at rated condition and no initial load is shown in Appendix I. The results of application of this procedure for the five machines (employing the median line of Fig. 8) are shown in Table VIII with a mean accuracy of 123%.

Approximate procedures were also applied to the calculation of the initial rate of rise of armature and shunt field current as shown in Appendix I. Comparable results to those obtained under the sample calculation were attained and are shown in Table IX with a mean accuracy of 90% and 127% for the armature and shunt field circuits respectively.

In Appendix II it is shown that by normalizing the no-load saturation curves for the five machines it is possible to employ generalized values for various constants and to develop a simple equation to represent the saturation curve.

Conclusions

Based on a comparison of test and calculated data on five machines, it is concluded that the accuracy in the computation of armature and field currents is as follows:

1. Peak armature current is within 105%±10% for 90% of the runs on the average if there is no flashover.
2. Peak field current is within 90%±20% for 90% of the runs on the average.
3. Initial rates of rise of armature and shunt field currents are variable with a mean of 90% and 127% respectively.
4. Time to peak for the armature and field current is highly variable. Instead, the time to reach and remain above 90% of the peak value will provide realistic information.
5. Peak armature current by approximation processes requiring a small number of design constants is feasible provided the reduced accuracy is acceptable.

Complete confidence in the method presented here and in the accuracy to be expected can only be established by a comparison of computed and test results on a large variety of d-c machines.

Appendix I. Approximate Calculations

The method of calculation for short circuit from design constants is reasonably accurate for all practical purposes, but is open to the objection that a large number of design constants are required, and the computation is involved and cumbersome.

Approximation of r_x'

Many design constants are used in the computation of r_x', a fictitious resistance which, when multiplied by the peak armature current, represents the loss in generated voltage. A rough approximation to this loss in generated voltage when a machine is short-circuited at any voltage, rated speed, and no load is one-third the voltage at which it is short-circuited. It is also found from tests and the equation derived for r_x' that the loss in generated voltage is almost directly proportional to the speed of the machine. Then a rough approximation of E_x', the loss in voltage due to short circuit at peak short-circuit current, may be expressed as

$$E_x' = (E_0/3)(N_0/N_1) \text{ volts}$$

Hence the generated voltage at peak short-circuit current is

$$E' = E_0(1 - N_0/3N_1) \text{ volts} \qquad (12)$$

The peak short-circuit current is then

$$I_x' = E_0(1 - N_0/3N_1)/R' \text{ amperes} \qquad (13)$$

Applying equation 13 to the machines tested at rated conditions, no load (in Table VII) the results are compared with test data and are shown in Table VIII.

Approximation of $E_r b$

At the present time, the reactance voltage E_r and the number of segments b spanned by the brush are utilized as per equation 6 of reference 1 to calculate an effective transient increase in armature winding resistance due to poor commutation. If the value of E_r, which is obtained most reliably from the manufacturer, is not available it can be calculated from any one of a number of equations, which are at best estimates. A list of some of these follow

$$E_r = 12 n_0 I_{a1} 10^{-6}/d_a \text{ volts} \qquad (14)$$

$$E_r = C_r KW_a/d_a \text{ volts} \qquad (15)$$

where

$C_r = 0.12$ for large machines
KW_a = power developed by the armature, kilowatts

$$E_r = 6.38\,AT\,l\pi d_a N_1 10^{-6}/g_c\,60 \text{ volts} \qquad (16)$$

where

AT = net difference of ampere-turns at rated load of armature and compensating windings
g_c = length of air gap beneath interpoles, inches
l = length of armature stack, inches

For simplex lap windings with full pitch turns

$$E_r = 0.33\,\frac{Z^2 N_1 I_{a1}}{Bab}(d_s + 0.1 l_e)10^{-6} \text{ volts} \qquad (17)$$

where

b = number of segments covered by the brush rounded off to the next higher integer
l_e = length of end connection for each conductor, inches

For simplex wave winding

$$E_r = 0.17\,\frac{Z^2 N_1 I_{a1}}{Bab}(d_s + 0.1 l_e)P10^{-6} \text{ volts} \qquad (18)$$

Equations 14 through 18 are different with each developed from definite assumptions and dependent on what data are available. If neither an estimate of E_r nor b is available the following method is recommended.

In the recent literature[4] there has appeared an equation

$$J/J_0 = 16\pi f a_1 h^2/3 s b_1 \qquad (19)$$

expressing a ratio of the commutation loss to the d-c loss of the armature winding. Equation 19 is based on the lag in flux reversal and nonuniform distribution of current in the conductor with assumption of instantaneous commutation where the energy involved is either lost during the commutation period at the contact surface (between the commutator segments and brushes) or within the armature conductors.

Equation 19 is rewritten to express the ratio of the increase in armature winding resistance to the d-c ohmic value

$$R = 0.054 a_1 f h^2/b_1 \qquad (20)$$

where h is in inches and a value for s, the specific resistance for copper, is used. This ratio is next incorporated as an increase in the effective transient armature winding resistance as follows

$$r_b' = (R-1)R_a n_0/R_1 + V_c/E_1 \qquad (21)$$

If it is desirable to include the effects of load, equation 21 may be rewritten as

$$r_b' = (K_l^2 n_0 V_a' + V_c)/E_1 \qquad (22)$$

where

$$V_a' = (R-1)R_a I_{a1} \text{ volts} \qquad (23)$$

Equation 22 is of the form of $(\alpha + V_c)/E_1$ so that Fig. 1 of reference 1 may be used to aid in evaluating r_b' whenever α is as small as the plotted values of α. This procedure for approximating $E_r b$ by equations 20, 22, and 23 was applied to the five machines and the results compared with test data as shown in Table VIII.

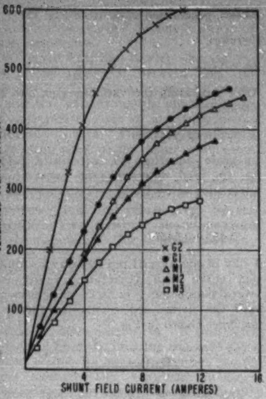

Fig. 9 (left). No-load saturation curves for five machines. Abscissa has been multiplied by 2 for M-3

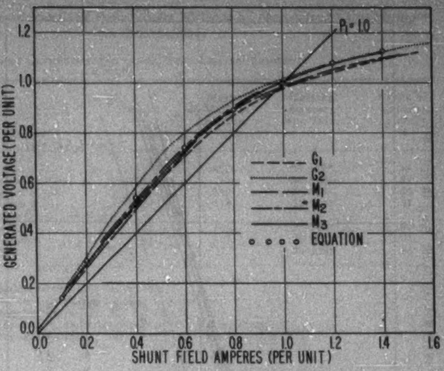

Fig. 10 (right). Normalized no-load saturation curves for five machines

Approximation of Peak Armature Current

In the preliminary design of a d-c power system only the voltage and current of machines are known and in order to have some idea of design requirements under fault conditions an estimate of the value of peak short circuit of each machine is required. It is known from experience that the maximum current of a d-c machine on "solid" short circuit is about 7 to 12 times rated current. In general, the higher values apply to 600 to 1,500-volt machines and the lower values to 125 to 250-volt machines. This rough approximation is shown graphically in Fig. 8 where peak short-circuit current, represented by the median line, is plotted against rated machine voltage. The other two lines shown in this figure have been arbitrarily drawn at 25% above and below the median line, and are suggestive of the band within which the actual maximum short-circuit current of most machines will fall. A comparison of test values of peak short-circuit current and the values as obtained from the median line of Fig. 8 are shown in Table VIII.

Approximation of Initial Rates of Rise

It is not always necessary to obtain a full solution for the transient armature current in order to compute the initial rate of rise. An approximation to the initial rate of rise of armature current may be calculated from the following equation

$$di/dt = E_0/(L_w + L_s) \text{ amperes per second} \tag{24}$$

Application of equation 24 to machine G-2 listed in Table IX results in

$$di/dt = 270/(310 \times 10^{-6}) \text{ amperes per second}$$

It is also possible to approximate the initial shunt field current rate of rise by utilizing this estimate of the initial rate of rise of armature as shown in the following development. Ratio of field to armature rate of rise is estimated by

$$N_{se}/N_f = I_{f1}(K_s'K_1 \pm m_{s1})/I_{a1} \tag{25}$$

where the plus and minus sign is for differential and cumulative action of the series field. Equation 25 written on the basis of unity coupling is rewritten as: Shunt field rate of rise is equal to

$$di/dt = I_{f1}(K_s'K_1 \pm m_{s1}) \text{ armature rate of rise}/I_{a1} \text{ amperes per second} \tag{26}$$

Application of equation 26 to G-2 listed in Table IX results in

$$di/dt = 6.7(0.155 + 0.17)870{,}000/1{,}150 = 1{,}650 \text{ amperes per second}$$

If there is no value of armature circuit inductance available, the following procedure is suggested to obtain an estimate of the armature winding inductance. Let

$$L_w = C_z L_{w1} \tag{27}$$

where

$L_{w1} = 19.1E_1/I_{a1}N_1P$ (from reference 5) machine base inductance in henrys

with generalized values for C_z (from reference 6).

Appendix II. Normalized Saturation Curves

A study was made to see whether generalized values may be employed successfully for some parameters which are now determined directly or indirectly from the no-load saturation curve of rotating machinery. No-load saturation data were obtained at base speed for the five machines tested and are shown plotted in Fig. 9. All machines begin to exhibit the typical saturation characteristic in the vicinity of base field current.

In an attempt to improve this similarity the abscissa and ordinate values of the original saturation data were divided by the appropriate base current and base voltage for each machine. This normalized data may be viewed in curve form in Fig. 10. These normalized curves show good agreement as to shape and lend themselves to the setting up of generalized values for K_1, K_2, Δp_0, and Δp_1. That these saturation curves come close to each other is attributed to design procedures whereby the operating point is generally "on the knee" of the saturation curve as a compromise between full utilization of the magnetic structure and high magnetic core losses.

Another worth-while feature in connection with the curves is the relation between the incremental permeance and static permeance. This relation was sought by obtaining the quantities E_0/I_{f0} and dE_0/dI_{f0}, at each integral current step from the data in Fig. 9. These new data were then further normalized into a pu system by employing the voltage and current base of each machine. It was found that there is an inverse correlation between K_1 and the incremental slope at base field current. In fact, when the reciprocal of K_1 is taken simply to the third power, the computed Δp_1 is in good agreement with the actual slope in pu at base field current. These

Table X. Comparison of Incremental Permeances

			Saturation Curve Slope				
			$dE_1/d(I_{f1})$		Approximation		
Machine	E_1/I_{f1}, Volts per Ampere	N_1, RPM	Volts per Ampere	Pu	K_1	$(1/K_1)^3$	% Accuracy
G-1	45.5	750	19	0.418	1.25	0.513	123
G-2	77.6	1,200	27	0.348	1.47	0.318	91
M-1	38.4	1,300	14	0.364	1.32	0.435	119
M-2	34.5	280	15	0.435	1.27	0.487	112
M-3	116	1,750	48	0.413	1.31	0.444	107

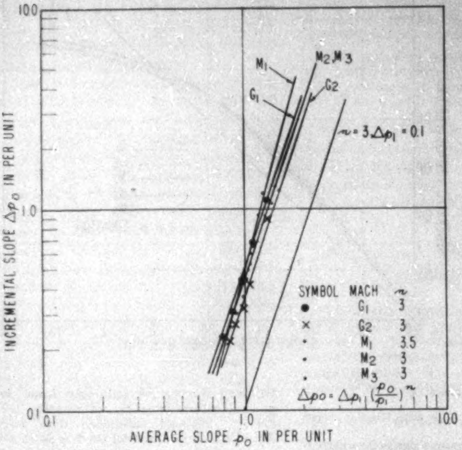

Fig. 11. Relations of incremental slope to the average slope of a no-load saturation curve

comparisons are shown in Table X.

The relation given by equation

$$\Delta p_0 = \Delta p_1 (p_0)^3 \tag{28}$$

was found by making a plot of the normalized incremental slopes versus the average slopes to the saturation curves. As shown in Fig. 11 these plots for four of the five machines were approximated by straight lines of a slope of three, indicating a cube power law. In addition, the intersection of these lines with the abscissa of 1.0 provides a check as to the magnitude of Δp_1. An assumption is made that equation 28 may be employed with p' in place of p_0 to obtain $\Delta p'$. As this relation between the incremental slope and the average slope of a saturation curve was satisfactory, the development was extended to the writing of an equation for representation of the no-load saturation curve.

Essentially equation 28 expresses

$$de/di = dp_1 (e/i)^3 \tag{29}$$

From the previous material when $i = 1$, $e = 1$, $dp = (1/K_t)^n$, where

$K_t = 1.3$, generalized value from Fig. 10

$n = 3.0$, generalized value from Fig. 11

therefore

$dp_1 = 0.455$

After separating the variables equation 29 becomes

$$\int de/e^3 = dp_1 \int di/i^3 \tag{30}$$

Integrate equation 30, substitute 0.455 for dp_1, and determine the constant of integration at $i = 1$ and $e = 1$ to arrive at

$$e^3 = \frac{i^3}{0.455 + 0.545 i^3} \tag{31}$$

A plot of equation 31 representing a saturation curve with generalized values for several parameters is in excellent agreement with the normalized curves for the five machines shown in Fig. 10.

Discussion

Donald T. Bewley (General Electric Company, Schenectady, N.Y.): Figs. 1 through 6 show that the agreement between tested and calculated transient curves is not as close as might be desired. This in itself is not as discouraging as it may seem since the sustained current is not reached before either flashover occurs or the circuit breaker operates; hence, the important items to be accurately calculated are peak armature current and maximum rate of rise of armature current. For industrial machines utilizing circuit breakers, an accurate determination of these items will assure proper selection of breakers that will interrupt the armature circuit before injury to the system apparatus occurs.

The test results indicate that the authors have made an important contribution to an accurate determination of peak armature currents. Closer agreement between test and calculated values of maximum rates of rise of armature current might be realized if a more accurate determination of machine inductance could be utilized. For the designer having machine parameters at his disposal, the determination of armature circuit inductance by the method of Snively and Robinson[1] has been found to be fairly reliable. Use of equation 27 of the present is not too reliable because of the wide variation in values of C_x for different machines.

The authors have indicated a method of including the effect of initial load on the peak value of short-circuit armature current. This is an important contribution since it shows that the effect of initial load on generating machines is to raise the peak armature current. The effect of initial load on motoring machines, on the other hand, is to lower the peak armature current. It has been the practice, in some circles, to ignore initial current and calculate the short-circuit armature current on the basis of zero initial load. Superposition of rated load on a d-c machine, expressed in pu as +1 for generators and −1 for motors, was assumed to be applicable if the no-load peak short-circuit current values were known. The results given in Table VII indicate that such a procedure would give acceptable results; therefore, for rapid calculation this method seems to be justified. Of course, test data on other machines are required to substantiate the method fully.

Mr. O'Connor and Mr. Cybulski have given us a refined method of determining short-circuit performance. They are to be complimented for their contributions.

J. P. O'Connor and J. Cybulski: As indicated by Mr. Bewley, the transient plots in Figs. 1 through 6 do not showas close agreement in all cases as might be desired. It should be emphasized, however, that the runs selected for these transient plots are not typical but rather those that show the greatest divergence. In Table III it will be noted that the results in general are good and compare well with the test values. Where the results are poor, as in run 41F, the machine was operating at a speed 20% above rated speed, which is hardly typical of actual operating conditions. The transient plotted in Fig. 3 for run Alc is for a low value of initial voltage and the resulting value of peak short-circuit current is small and equal to the steady-state value. For the applications engineer, interested in selecting circuit breakers, initial conditions that result in a short-circuit current equal in value to the normal steady-state value of short-circuit current (about 3 pu) is of little importance.

We agree with Mr. Bewley that reasonably close agreement between test and calculated values of maximum rates of rise of armature current may be obtained when an appropriate value of armature circuit inductance is used. The values of machine inductance used in the paper were those supplied by the manufacturer. These values were checked using a-c measurements (60 cycles) and found to be in close agreement with the values given by the manufacturers. However, the value given by the manufacturer for M-3 was obviously too low (5 microhenrys). In the paper a value of 2,300 microhenrys obtained by a d-c incremental flux method was used for M-3. A subsequent measurement of machine inductance by the a-c method gave a value of 900 microhenrys. If this latter value had been used for the transient plots (Figs. 5 and 6) better agreement would have resulted. Our experience indicates that values of inductance obtained by 60-cycle a-c measurements give satisfactory results when compared to test values of the maximum rate of rise. It should be emphasized, however, that the calculated or measured value of unsaturated armature circuit inductance does not truly represent the machine inductance under all initial conditions. For example, the effect of initial load on a machine reduces the armature circuit inductance because of saturation effects.

Equation 27 is not an accurate method for calculating armature circuit inductance because of the difficulty in obtaining a reliable value of C_x applicable to a particular class of machines; it was suggested only as an approximate and convenient method when a more accurate value could not be obtained. The ease with which calculations can be made by using this equation whenever design details are unavailable for the computations indicated by Snively and Robinson needs no defense. Further, if the values of inductance as obtained by equation 27 are compared to the values obtained by the Snively and Robinson method for the large number of machines listed in reference 6 of the paper, good agreement is found. This of course is not surprising since the generalized values for C_x are based on the calculated results obtained mainly by the Snively-Robinson method.

It appears to us that for clarity in analysis and discussion two terms which cause considerable confusion in short-circuit work should be clearly defined. These terms are the initial or maximum rate of rise of short-circuit current and time to peak armature current. Measuring the current slope at time zero on an actual oscillogram of a short circuit is a matter of considerable difficulty and it is not surprising that different observers will report slopes that differ considerably. In any event, the initial slope is of little practical value unless it is representative of the average rate of rise up to a particular value of the transient armature current. If the maximum or initial rate of rise of armature current is defined and measured as the average rate of rise from the time of initiation of short circuit up to the time when a fixed fraction of peak armature current (say, one-half) is reached, then this rate of rise would have a definite meaning and would be of practical use. Similarly, the time to peak armature current means little unless it is definite and has practical utility. For example, in a short circuit where the armature current remains near its peak for a relatively long time the time to peak is indefinite and not easily discernible. For this reason it is obvious that the time to reach a fixed fraction of peak armature current (say, nine-tenths) would be more practical and desirable from the point of view of those concerned with circuit-breaker application.

Table XI. Comparison of Exact and Approximate Methods by Short-Circuit Calculations on Five D-C Machines

Rated Conditions, No Loads, Zero External Resistance

No.	Method	Required Basic Constants	Mean 5-Machine Accuracy, %	Machine Accuracy Min.-Max., %	Range of Machine Accuracy, %
1	exact	25	107	92–119*	27
2	approximation of E_rb	26	95	80–112*	32
3	approximation of r_x'	7	119	95–159	64
4	approximation B	6†	118	92–143*	51
5	median curve for r_d' (ref. 6 of the paper)	4†	155	97–248*	151
6	approximation A	4†	127	85–290*	205
7	curve for i_a'	1	117	75–168*	93

* Error on machine M-2.

† A motor requires one additional constant (horsepower).

No. 3 approximation of r_x' requires E_1, I_{a1}, N_1, R_w, E_r, b, and V_c.

No. 4 approximation B requires E_1, I_{a1}, N_1, R_w, R_a, and P.

No. 5 r_d' curves require E_1, I_{a1}, N_1, and a knowledge of pole face windings.

No. 6 approximation A requires E_1, I_{a1}, N_1, and P.

The adding or subtracting of 1 pu armature current for motor or generator respectively to account for the effect of an initial 1 pu load condition (the initial computation for peak short-circuit current being made on the basis of zero initial load) is considered to be a reasonably accurate method of estimating the peak short circuit if it is a zero external resistance short circuit and if the machine is initially at or near its rated speed and voltage. In extrapolating the test values of peak short-circuit current for the initial conditions of no-load rated voltage and rated speed for motors M-1 and M-2 in Table VII an increase of 1 pu was added to the test values obtained at rated load and rated conditions. In most cases the effect of flashing or flashover prevents exact experimental verification of this procedure.

Approximation procedures were developed in this paper in order to enable estimation of peak short-circuit currents whenever design data are limited. After completion of this paper, this work was expanded as estimates of short-circuit current are often desired during design of power systems. The various approximate procedures are compared with test data and the significant results appear in Table XI. Procedures A and B were developed. Briefly, they result from the application of empirical equations extending the approximation of E_rb in combination with the approximation of r_x' in this paper. The end result is that

$$r_d'=\frac{3}{2}(r_w+r_b')$$

approximating r_x' by one-third r_d'.

$$r_b'=\frac{V_b}{E_1}$$

with

$$V_b=\alpha\left(\frac{\epsilon^{\alpha/b}+1}{\epsilon^{\alpha/b}-1}\right)+V_c \text{ volts}$$

(with V_c assumed equal to 2 this expression may be evaluated using Fig. 1 of reference 1 of the paper)

where

$$\alpha=V_a'=(\mathfrak{R}-1)R_aI_{a1} \text{ at rated speed, no load}$$

with

$$\mathfrak{R}=0.67PN_1Q^2 10^{-9}$$

and

$$Q=350\left(\frac{KW_a 10^3}{N_1}\right)^{0.14}$$

ampere conductors per inch of armature periphery. The KW_a term is $E_1I_{a1}/1{,}000$ for a generator, 0.746 horsepower for a motor.

A system for rating all seven methods listed in Table XI with some figure of merit should take into account the number of basic constants, the absolute value of the difference between the mean machine accuracy and 100%, and the range in machine accuracy. One basis would be to assign an equal weight to each one of those statistics. A summation of the numerical value of each of the three statistics for each method would indicate a figure of merit. Assuming that the number of basic constants is most important, the

Table XII. Figure of Merit and Rating of the Methods

No. Method	Equal Weight		Unequal Weight	
	Merit	Rank	Merit	Rank
1	59	1	28.4	6
2	63	2	29.7	7
3	90	4	15.3	3
4	75	3	12.9	2
5	210	6	24.6	4
6	236	7	27.2	5
7	111	5	12.0	1

other two statistics may be given a weight of one-tenth their value. On this basis another figure of merit can be computed. Both of these rating systems were applied to the data of Table XI with the results shown in Table XII. The methods are ranked with the lowest figure of merit the best procedure. With equal weight attached to the statistics, methods 1 and 2 are best with methods 3, 4, and 7 close behind. With the greater weight attached to the number of constants, methods 3, 4, and 7 are equally good and considerably better than all the other methods. Either system for establishing a figure of merit indicates that the recommended approximations at the present time are methods 3, 4, and 7.

We wish to thank Mr. Bewley for his discussion, which emphasizes the important practical reasons for short-circuit calculations and affords us the opportunity to clarify some additional questions not treated in the paper.

Turbine Generator Stator-Winding Temperatures at Various Hydrogen Pressures

C. E. KILBOURNE
FELLOW AIEE

D. S. SNELL
MEMBER AIEE

Synopsis: The power industry has for years accepted certain general principles upon which temperature limits are based in the rating of electrical machines and apparatus. AIEE Standard No. 1[1] sets forth the philosophy to be followed in selecting the permissible total temperatures at various locations within machines, dependent upon the class of insulation employed. The particular values of allowable temperatures and the locations at which they shall be measured in cylindrical rotor machines are stated in the American Standards Association Standard (ASA) C50.[2] Both of these standards established their recommendations many years ago, when turbine generators were all air-cooled machines and the industry's experience on the performance and life of such machines was a dominant factor in the selection of allowable temperatures.

In 1937, when turbine generators began to be hydrogen-cooled, the allowable temperatures established for air-cooled machines and the temperature differences between the measurable temperatures and the hot-spot temperatures were tacitly assumed to be correct for the new type of cooling at a hydrogen pressure of 1/2 pound per square inch gauge (psig) in spite of a load increase which was realized with hydrogen cooling. With time, the practice of operating machines at hydrogen pressures higher than 1/2 psig has become quite general. Also for some years a number of machines have had their ratings based on capacities associated with increased hydrogen pressures, and there is no industry standard which recognizes the proper allowable measurable temperatures and temperature rises. Thus there are two conditions, one applying to operating machines whose ratings have been set at 1/2-psig hydrogen for increased capabilities at higher hydrogen pressures, and another, the establishment of proper temperatures for machines rated at higher than 1/2-psig. This indicates a need for increased knowledge on the temperature behavior of turbine generators.

Several years ago, an analysis was presented of the temperatures and temperature rises in turbine generator windings, including both a theoretical approach to the problem of determining the temperature conditions and a comparison of test and calculated results on a particular machine.[3] Since that time the theoretical approach has been refined and additional tests have been made in which actual copper temperatures were measured. This paper presents the results of the last several years' work, adding to the accuracy of the theoretical approach, and giving additional comparisons between tests and calculations. Thus it is intended as a contribution to the increased knowledge needed on the temperature behavior of turbine generators. In addition, since many data are now available on the temperatures existing at 15- and 30-psig, as well as at 1/2-psig hydrogen pressures, certain principles which should apparently underlie the allowable temperatures to accompany higher than 1/2-psig ratings are proposed. These principles are offered as a basis for revision of the ASA C50 standard to take account of the increased temperature drop from hot-spot copper temperature to detector temperature at elevated hydrogen pressures.

THE almost universal use in this country of hydrogen as a cooling medium for large turbine-driven generators, and the expanding use of increased casing pressure to obtain increased outputs from a given size of machine have created a need for an extended understanding of the temperatures and temperature rises which exist throughout such structures. This need is particularly pressing with respect to temperatures in the vicinity of the armature windings because the highest temperature in contact with the insulation, the temperature of the copper of the coils, cannot be directly measured with practical devices available at present. Hence, it is now necessary to establish an allowable rise, by resistance temperature detectors, for various conditions of operation, which will give assurance that the total temperatures, which are not now directly measured, will be satisfactory.

Today the two standards AIEE No. 1 and ASA C50[1,2] exist as guides to establishing the permissible temperatures throughout large machines. The AIEE No. 1 in particular defines the philosophy underlying the proper selection of temperatures. Neither of these standards, however, takes full account of the conditions existing in hydrogen-cooled turbine generators, as both were created before the advent of these machines. Therefore, the problem that exists today concerns the application and extension of these standards to take account of conditions as they are now. In particular, what should be the allowable copper temperature (hottest spot) in the armature windings of these machines; what resistance temperature detector rise should be associated with this hottest spot; how does the use of hydrogen cooling and increased loading associated with 1, 2, and 3 atmospheres absolute casing pressure of the cooling gas affect these temperature limits; and what happens to the ambient cool gas temperatures as casing pressure changes, are questions that need answering today. But first, what is the philosophy expressed by AIEE No. 1 which may be used as a guide and an approach to the problem?

AIEE No. 1 has recently been undergoing a reappraisal and revision to include

Paper 55-118, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 15, 1954; made available for printing December 7, 1954.

J. R. M. ALGER, C. E. KILBOURNE, and D. S. SNELL are with the General Electric Company, Schenectady, N. Y.

The authors wish to acknowledge the support and encouragement given them by their associates in the General Electric Company who contributed materially to this paper, particularly L. P. Shildneck, C. H. Holley, I. J. Dilts and D. J. Herder for test information generously made available, and R. S. Neblett, H. D. Taylor, E. D. Huntley, B. M. Cain and J. H. Carter for their encouragement in the preparation of the paper and their critical review of its contents.

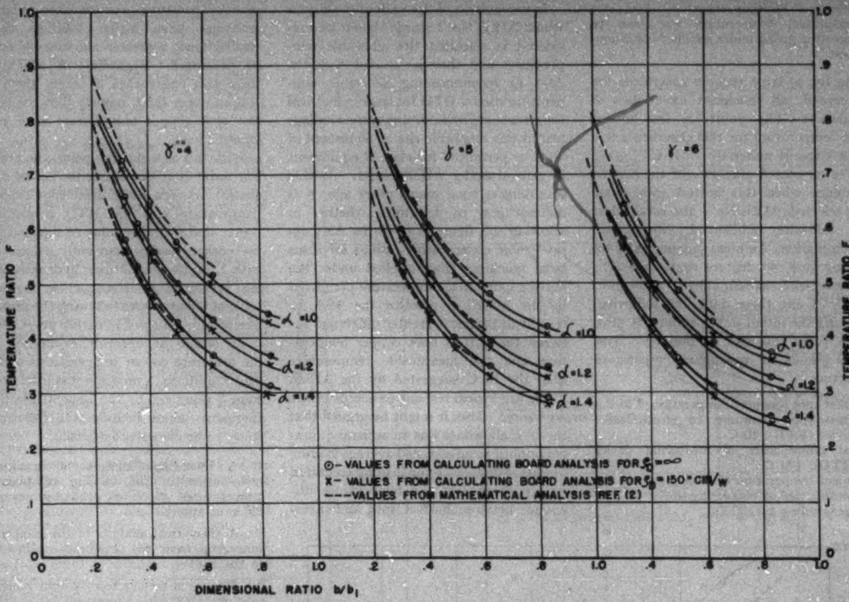

Fig. 1. Values of the ratio F for different values of b/b_1, α and γ for $r=0$, for $\rho_D=150$ C inch per watt, and for $\rho_D=\infty$. From calculating-board analysis, with values from mathematical analysis shown for comparison

knowledge gained in recent years. In its revised form, recently presented, it represents the most modern thinking on the selection of proper temperatures for various service conditions and various classes of insulation used throughout industry. To quote directly:

"This pamphlet. . .deals with the general considerations upon which the temperature rise limits in. . .standards are based. The principles... are intended to serve as a general guide in the preparation of the various standards for specific types of equipment, and it is recognized that variations from the numerical values of temperature rise given are desirable in particular cases. . .it is recognized that rating limits are most useful if they indicate feasible outputs for equipment under usual service conditions. A principal determining factor in establishing temperature rise limits is the thermal endurance of the insulating materials employed, but numerous other factors must be considered."

These other factors include consideration of the following:

"1. Insulation does not fail by immediate breakdown upon arrival at a critical temperature but by gradual deterioration with time. Therefore, the question of how hot an insulation can be operated can be answered only on the basis of how long it is desired to have it last...

2. The electrical strength of insulation cannot be directly correlated with the mechanical strength...physical disintegration [with heat or from other causes] finally results in electrical failure...In view of the important influence of mechanical stresses, thermal expansion and contraction forces impose temperature rise limitations on larger equipment, even though higher temperature rises [for a given class of insulation] have proven to be satisfactory in small machines.

3. Insulation life is dependent to a considerable extent upon the access of oxygen, moisture, dirt or chemicals to the interior of the insulation structure...Particularly favorable results are indicated from the use of chemically inert gases as cooling or protective media.

4. ...the useful life of insulation is [dependent on the] percentage time the equipment is used, and the degree of loading when used.

5. Insulation life depends on the treatment the insulation receives during manufacture and installation...

6. It is also important to realize that the physical deterioration of insulation, under the influence of time and temperature, increases very rapidly with temperature. [Tests on] Class A insulation in air-exposed rotating machines...indicate that roughly 10 to 12 C increase in temperature halves the life. For other classes of insulation [under varying conditions] a similar change in life is observed at varying temperature increments..."

The Standard outlines the following basis for the assignment of temperature limits:

"1. [It is necessary to classify] insulation systems or their component materials in terms of the limiting temperature which can be reasonably assigned to them in continuous service, or for a desired period of expected life.

2. [It is necessary to select] a reasonable value of limiting ambient temperature which, subtracted from the limiting temperature [item 1] gives limiting values of temperature rise.

3. [In order to use temperature indicating instruments, it is necessary to establish] nominal temperature differences between the temperatures read by the various practical temperature measurement methods, and the limiting insulation temperatures at the selected values of limiting temperature rise.

4. [After establishing these temperature

differences] limiting values of observable [measurable] temperature rise [can be assigned] a rating under specified conditions of test."

As far as large turbine generators are concerned, all machines have class *B* insulation. The value of the hottest spot temperature for this classification is "For Class B material. . .130 C."

For air-cooled machines of the sizes in existence when this hottest spot value was selected, AIEE No. 1 also established the following additional temperature bench-marks: Ambient temperature (of cooling gas), 40 degrees centigrade (C); hottest spot measurement allowance, 10 C. Using these data, the following, showing the intent of the standards as of some years ago, can be derived. Here RTD stands for resistance temperature detectors.

Hottest spot (copper) temperature, 130 C.
Hottest spot allowance to measurement device (RTD), 10 C.
Total temperature of measuring device (RTD), 120 C.
Ambient temperature of cooling gas, 40 C.
Allowable rise of measuring device (RTD) over cooling gas, 80 C.

In recognition of the various conditions which AIEE No. 1 stated should be considered in selecting the allowable temperatures and their associated rises, the ASA in recommending allowable temperature rise by RTD for large cylindrical rotor turbine generator armature windings placed this allowable rise at 60 instead of 80 C as permitted for class *B* equipment in general under AIEE No. 1. As this was done a good many years ago, it is difficult now to determine whether in selecting this figure of 60 C the ASA desired more conservative ratings for these large machines than applied under the hottest spot 130 C temperature permitted by the AIEE, or whether the ASA intended to permit a greater difference between the hottest spot copper temperature and the measurable temperature than the 10 C suggested by the AIEE. There are logical reasons to accept either approach. Also, it might be argued that the 10 C allowance was an arbitrary number applied to an assumed average loading condition and, since the loading condition largely determines the temperature difference between hottest spot and measured temperatures, and therefore as large machines have higher loadings than smaller ones, a greater allowance should be permitted. Regardless of which of these two approaches is taken, there is still an upper limit, namely that the hottest spot copper temperature shall not exceed 130 C.

With this as a starting point, the problem today is to determine the actual difference between the hottest spot copper temperature and the RTD measuring point; and with this value established for the various loadings currently associated with 1/2-, 15-, and 30-psig hydrogen casing pressures, to construct a modern table of temperatures following the principles so ably outlined in earlier years.

To obtain an accurate evaluation of the armature copper temperatures under load conditions, a program was instituted some 3 years ago by the General Electric Company which includes the following steps, to be discussed in detail.

1. A theoretical analysis of armature temperature in the vicinity of highest temperatures as determined by several different approaches.
2. A theoretical analysis of the temperature drop from the armature conductors to the RTD's.
3. A series of factory tests on four generators provided with thermocouples on the armature conductors as well as the usual RTD's.
4. Field tests on two of the factory-tested generators in order to evaluate the armature conductor and air-gap temperature rises under actual load conditions and to coordinate these data with the previous theory and the factory data.

This program has permitted some analytical and experimental evaluation of the several factors which determine the temperature rise of the armature winding and the temperature drop from the copper conductors to the temperature detectors.

Conclusions

1. Hottest spot copper temperature is intended by the Standards as the starting point for selecting the temperature rises associated with establishing a rating for a machine. In hydrogen-cooled turbine generator armature windings the hottest spot copper temperature selected should be a constant value, independent of the hydrogen casing pressure selected as a condition of the rating.
2. Theoretical studies, checked by tests, have produced a satisfactory method of determining the temperature difference between the hottest spot copper temperature and the temperature of the practical measuring device, the RTD.
3. These studies and tests indicate that as copper loadings, and therefore losses,

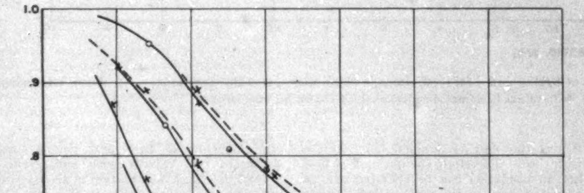

Fig. 2. Values of the ratio F for different values of b/b_1 and γ, for $\alpha=1$, $\rho_D=\infty$, for $r=0$ and $r=0.14$ inch from calculating-board analysis

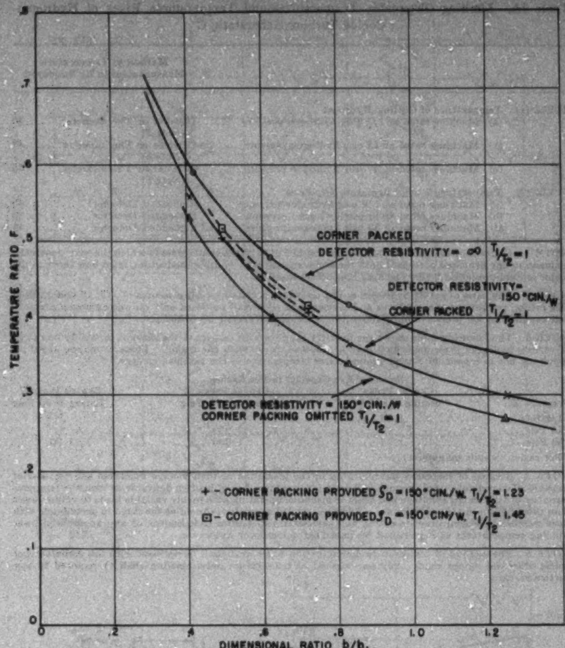

Fig. 3. Values of the ratio F for different values of b/b_1 for $\alpha=1$, $\gamma=5$, $r=0.14$ inch. For corner packing provided and for corner packing omitted. Exposed bar corner and detector surfaces at temperature of tooth iron. For three values of T_1/T_2, for $\rho_D=150$ C inches per watt, and for $\rho_D=\infty$. From calculating-board analysis

increase, which is customary practice as hydrogen casing pressures increase from 1 to 2 or 3 atmospheres, the difference between hottest spot copper temperature and the RTD temperature increases rapidly, approximately as the square of the ratio of the copper loading at the several casing pressures.

4. With the proportions used at present for economical cooler design, and holding constant cooling water conditions, the ambient temperature of the cooling hydrogen rises a few degrees as the machine loading increases at the higher casing pressures.

5. Therefore, considering conclusions 1 to 4, it is obvious that to hold constant hottest spot copper temperatures as loads increase with hydrogen casing pressure, the allowable rise of the RTD over the ambient cooling gas temperature must decrease.

6. From the theory and test data presented here, together with data from other sources, a working group under the sponsorship of the ASA C50 Committee has proposed a table of allowable cold gas and RTD rises at various loadings and hydrogen casing pressures for hydrogen-cooled turbine generators. This paper discusses their proposal, quotes the table, and advocates the acceptance of the temperatures and temperature rises given in the table.

7. With respect to machine performance and the effect of hydrogen pressure on the temperatures existing in various parts of the machine, the following points are of interest:

a. The temperature difference across the ground insulation is the principal factor in determining the differences between hottest copper temperature and RTD. Other temperature to be considered is the temperature distribution throughout the copper inside the insulation, and the thermal field adjacent to the sensitive element of the RTD.

b. The thermal field adjacent to the RTD element can be determined as a function of the geometry and materials used in the slot area.

c. With adequate packing of the space between the corners of the armature bars and the RTD, heat dissipation from the side surfaces of the RTD to the cooling gas has negligible effect on the RTD readings in slots of the width common in turbine generators (approximately 1 inch or more).

d. With adequate packing of the RTD, the temperature drop from copper to RTD, for a given loading in a given machine, is independent of the hydrogen pressure.

e. Both the total copper temperature and the RTD temperature are basically related to the local temperature of the cooling gas in the vicinity of the tooth packet adjacent to the RTD locations in the generator.

f. The hottest spot in the armature winding is located in the top coil side adjacent to the hottest RTD, about halfway up the coil side and is, usually, for loads between 100 and 125 per cent (%) of normal, between 2 and 4 C hotter than the average temperature of the top coil side.

g. The average temperature of the top coil side may be approximately determined from the reading of the adjacent temperature detector, from the equation

$$\text{top coil-side temperature} = \text{RTD temperature} + (1-F)T_3 + \Delta T_c$$

where the values of T_3 and ΔT_c may be calculated, for a given load condition, from the equations given in the derivation of equations in the section "Theoretical Analysis of Armature Temperatures," paragraph 4. The value of F may be determined for the dimensions of the given armature bar, by reference to the curves in Figs. 1, 2, and 3.

1. Proposed Revision of ASA C50 Standards

Several years ago the ASA C50 Committee established a subcommittee to review the present C50-1943 standard for rotating electrical machinery and to recommend such modifications and changes as was deemed necessary to modernize the standard. One of the subjects for revision considered by the subcommittee was Table I of the standard covering permissible temperature rises of various classes of machines, and particular attention was directed to establishing the proper temperatures and temperature rises for hydrogen-cooled turbine generators.

Based on the theoretical and experimental data presented in sections 2 to 5, plus similar data from other sources, the sub-committee prepared a table and associated notes for the proposed revision of C50. Table IA is a part of the proposed table and notes applying to stator winding temperatures at various hydrogen pressures.

The authors wish to express their agreement with the proposed table and to urge

Table IA. Limiting Observable Temperatures and Temperatures Rises of Hydrogen-Cooled Turbine Generators, C

		Method of Temperature Measurement to Be Employed	
ITEM (1)	Temperature of Cooling Hydrogen		
	(a) Machine rated at 1/2 Psig hydrogen pressure	Detector or Thermometer (Note 5)	40
	(b) Machines rated at 15 psig hydrogen pressure	Detector or Thermometer (Note 5)	44
	(c) Machines rated at 30 psig hydrogen pressure	Detector or Thermometer (Note 5)	46
ITEM (2)	Temperature Rise of Armature Windings		
	(a) Machines rated at 1/2 psig hydrogen pressure	Embedded Detector	60
	(b) Machines rated at 15 psig hydrogen pressure	Embedded Detector	50
	(c) Machines rated at 30 psig hydrogen pressure	Embedded Detector	45

NOTE 1 Conventionally cooled machines are considered to be those machines in which the heat, generated by losses in any principal portion of both the armature and field winding conductors, must flow through the major ground insulation before reaching the cooling medium.

NOTE 2 The basis of rating hydrogen cooled machines is stated for H_2 pressures of 1/2, 15 and 30 psig. The rating, guaranteed temperatures and temperature rises shall be based only on one hydrogen pressure and capabilities for pressures only above the rated pressure shall be considered.

NOTE 3 The following table shows the industry practice with respect to the ratio of capability to rating at various hydrogen pressures which may be selected to establish the rating. These ratios are based on supplying not to exceed 90°F inlet cooling water temperature to the machine coolers:

	Ratios of Kva Capacity to Kva Rating		
Pressure X	Cap. at Press. X Rating at 1/2 Psig	Cap. at Press. X Rating at 15 Psig	Cap. at Press X Rating at 30 Psig
1/2 Psig	1.00	*	*
15 Psig	1.15	1.00	*
30 Psig	1.25	1.086	1.00

* For ratios, consult manufacturer.

NOTE 4 Because of increased thermal drop in the insulation of high voltage machines and because of mechanical considerations of thermal expansion in large machines, it is often desirable to limit the temperature rises of large or high voltage machines or machines operating with highly variable loads to values lower than those shown in the above table. Hydrogen cooled generators should be operated in accordance with their selected hydrogen pressure rating and associated capabilities independent of any apparently lower winding temperatures as determined by imbedded detectors or resistance.

NOTE 5 The method of temperature determination to be used shall be optional with the manufacturer unless otherwise agreed upon. Only one method of temperature determination shall be required in any particular case.

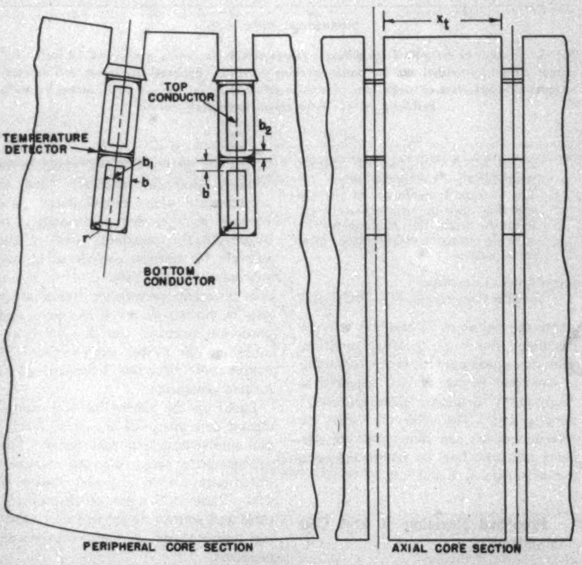

Fig. 4. Sketch of slot region and longitudinal section of a lamination package in a generator stator

its adoption. In interpreting and applying the data from this table to particular machines it should be noted that the values of limiting temperatures and temperature rises in any standard are the highest values permissible on any machine of the class, size, and type covered by the standard, and do not necessarily reflect proper operating procedures for all machines covered by the standard. Particular attention should be paid to note 4 where it is pointed out that temperatures and temperature rises lower than the values given in the standard may be advisable for certain large or high voltage, or variable load units. Especially in these cases, but also for hydrogen-cooled machines as a whole, safe operating practice should load the machines in accordance with their ratings and/or capabilities in kw, power factor (pf) and kva at various hydrogen-casing pressures. In these cases temperature rises lower than the maximum allowed in other cases covered by the standards can be established by tests in the user's plant, and if desirable these lower values can be used as guides to the performance of the unit.

2. Theoretical Analysis of Armature Temperatures

USING THE D-C CALCULATING BOARD

With generators using the multiple radial system of stator ventilation the hottest part of the armature winding is in the core discharge section nearest the center of the generator. Since the distribution of gas flow to the several vent ducts in a given section of the stator is fairly uniform, and since axial heat flow along the conductors may be accounted for in the calculation, an analysis of the heating of the armature winding and iron may be conveniently made through consideration of a unit section of the stator in the center discharge section, comprising a single slot pitch circumferentially and a single vent duct pitch axially. A sketch of a unit stator section is illustrated in Fig. 4. An analysis of the temperature rise of the armature conductors and iron above the temperature of the gas entering the radial vent ducts, for different conditions of load and hydrogen pressures, was made through use of the d-c calculating board. In this analysis the unit section shown in Fig. 4 was considered as represented by a network of thermal resistances as illustrated in Fig. 5. The losses in the unit section were assumed to be concentrated at various points as shown. On the d-c board the various thermal resistances were represented by ohmic resistances, the losses in the various sec-

tions as current flows, and temperature drops as voltage drops. The resistances were evaluated for one-quarter of a slot package, assuming no heat flow across the radial center lines of the slot and tooth and the axial centerline of the package. For the portion of the system where distributed heat flow was obtained, the thermal resistances were calculated on the assumption of parabolic temperature distribution. One-dimensional heat flow was assumed and the principle of superposition applied. Axial heat flow was not considered. Temperature rise of the gas in passing along the ducts was included. For the insulation in the coil corner, a separate analysis for the determination of the thermal resistance is shown in Appendix I.

In the calculating-board analysis, the temperature rises of the armature copper and iron were determined with respect to the temperature of the gas entering the radial vent ducts. This is the temperature of the gas in the air gap opposite the core discharge section. A method (not included here) for calculating the temperature rise of the gas in the air gap has been developed. The gap gas rise at the center of the generator is usually higher than the total gas rise through the generator, because of the rotor I^2R losses which are given up to the air gap in the center portion of the machine.

The results of the calculating board analyses are given in Figs. 6, 7, and 8. The temperature rises of the armature coil sides and iron at different radial positions, as determined from this study, for operation at rated load at 1/2- and 15-pound per square inch (psi) hydrogen pressure, are shown in Fig. 6. The average temperature rise of the top coil side is shown to be higher than that of bottom coil side, as a result of the higher eddy current losses in the top coil side. Fig. 7 gives the calculated radial temperature distribution in the two coil sides at two loads at 1/2-psi hydrogen pressure for two values of insulation thermal resistivity, corresponding to the maximum and minimum values expected to obtain in practice. Laboratory tests have indicated that the thermal resistivity of the ground insulation of a standard mica-insulated armature bar is determined largely by the density of the insulation when the bar is in final condition in the slot. It has been shown by test that the apparent thermal resistivity of the insulation may vary considerably, being as much as 170% of the dense insulation resistivity if proper care is not exercised in assembling and fitting the bar to the slot. The influence of duct gas rise on the winding temperature is also shown in Fig. 7, and is observed to be small. The calculated division of heat flow in the coil sides and iron, for operation at rated load of 1/2-psi hydrogen pressure, is shown in Fig. 8. It is observed that the major portion of the copper losses passes into the tooth iron and is dissipated from the duct iron surfaces. Also, some of the loss in the bottom coil side passes into the core body while some of the core body loss passes into the tooth. From this analysis and others for different loads and hydrogen pressures, it is evident that for closely approximating the winding temperature rises under load, the plane of division of radial heat flow in the tooth may be assumed to lie at a distance inward from the tooth root approximately equal to one-third the tooth height.

Equivalent Thermal Circuit

For convenience in predetermining the stator temperatures, equations for the numerical calculation of the temperature rises of the armature winding and iron above air gap temperature for a unit stator section were derived as shown in the following.

Calculation of Copper and Iron Temperature Rises Above Cold Gas Temperature for Thermal Circuit of Fig. 9

$$R_1=\frac{r_{bx}r_{by}}{r_{bx}+r_{by}}$$

$$r_3=\frac{r_{tx}r_{ty}}{r_{tx}+r_{ty}}$$

$$r_5=\frac{r_{cd}r_{cg}}{r_{cd}+r_{cg}}$$

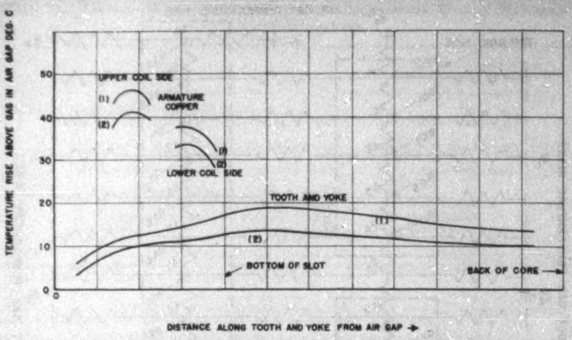

Fig. 6. Radial temperature distribution in top and bottom armature bars and in stator iron at rated load at 1. 0.5-psi; and 2. 15-psi hydrogen pressure for a unit stator section of a 111-mva 13.8-kv 3,600-rpm generator, as determined from calculating-board analysis

$A = r_3 + r_4 + r_5$

$B = r_3 + r_4' + r_{cd}$

$C = r_3 + R_1 + R_2$

$D = r_3^2(A+B+C) - 2r_3^3 - ABC$

$E = r_4 q_{ct} + r_3 q$

$F = r_4' q_{cb} + r_3 q$

$G = R_2 q_1 + r_3 q$

$q = q_b + q_t + q_{ct} + q_{cb}$

$q_1 = (1/D)\{r_3^2[G-(E+F)] + r_3(AF+BE) - ABG\}$

$q_5 = (1/D)\{r_3^2[E-(F+G)] + r_3(BG+CF) - BCE\}$

$q_7 = (1/D)\{r_3^2[F-(E+G)] + r_3(AG+CE) - ACF\}$

$q_3 = q - q_1 - (q_5 + q_7)$

$t_{ct} = r_5 q_5 + \theta_0$

$t_{cb} = r_{cd} q_7 + \theta_0$

$t_t = r_3 q_3 + \theta_0$

$t_b = R_1 q_1 + \theta_0$

$T_1 = t_{ct} - t_t$

$T_2 = t_{cb} - t_t$

$T_3 = 0.5(T_1 + T_2)$

$\Delta T_c = 0.5(t_{ct} - t_{cb})$

These equations are based upon the equivalent thermal circuit of Fig. 9. Mean values for the temperature rises of the coil sides, tooth, and core are assumed, and for the parts in which the heat flow is distributed, parabolic temperature distribution has been assumed. The surface of division for the radial heat flow in the iron has been assumed to be located inward from the tooth root by an amount equal to one-third the tooth height. By symmetry, heat division surfaces were also taken along the radial centerlines of tooth and slot and along the axial centerline of the iron package. Additional assumptions were made as follows:

1. Axial heat flow neglected.
2. Gas rise in duct neglected.
3. Heat flow from temperature detector to duct and tooth neglected.
4. Superposition applies.

The agreement between results obtained with this calculation method and with the calculating-board analysis is indicated by the following example.

Comparison of the armature copper temperature rises above air gap gas, as calculated by several methods for a 111-mva 13.8-kv 3,600-rpm generator operating at rated load at 1/2-psi hydrogen pressure, is as follows:

Average slot copper by method of reference 3, 38.5 C.

Top coil-side copper: D-c board analysis (average), 44.0 C; method described in section 2 ("Equivalent Thermal Circuit"), 40.7 C.

Bottom coil-side copper: D-c board analysis (average), 36.0 C; same method, 35.1 C.

For the calculation of the temperature rise of the bottom coil side the numerical calculation method checks the calculating board analysis closely; for the top coil side the agreement is not as close. However, from a number of calculation examples using both methods, it has been determined that the calculation method based on the equivalent circuit of Fig. 9 may be calibrated to yield results which are reasonably satisfactory.

NOMENCLATURE

Dimensions (Refer to Fig. 4)

b = thickness of coil-side insulation, including clearance space between coil side and slot wall
b' = thickness of ground insulation at top and bottom of armature bar
b_1 = over-all copper width inside insulation
b_2 = radial distance from edge of copper to center of temperature detector
r = outside radius of corner of armature bar
X_t = axial length of core package
α = ratio b_2/b

Equivalent Thermal Resistances

r_4 = path from mean copper temperature to slot wall, top coil-side
r_4' = path from mean copper temperature to slot wall, bottom coil-side
r_{bx} = path from mean core body temperature to vent duct gas (axial)
r_{by} = path from mean core body temperature to gas at back of core (radial)
r_{cd} = path from mean copper temperature to vent duct gas (axial), one coil side
r_{cg} = path from mean copper temperature to air gap (radial), top coil side
r_{tz} = path from mean tooth temperature to vent duct gas (axial)

ρ_D=temperature detector material resistivity

γ=ratio, transverse thermal resistivity of insulation ρ_i/longitudinal thermal resistivity of insulation

3. Calculating-Board Analysis of Temperature Drop from Armature Copper to Temperature Detector

A mathematical analysis of the temperature differential between armature copper and temperature detector is given in reference 4. In the following, an analysis made by use of the d-c calculating board is described, the results of which are shown to agree substantially with those of the mathematical analysis. Both analysis had for their objective the evaluation, for various design parameters, of the factor F, through which the temperature drop from copper to detector may be determined. This factor is defined by the equation

$$F=\frac{\text{temperature difference, detector to iron}}{\text{temperature difference, copper to iron}}$$

where the iron temperature is assumed to be the average temperature of the tooth iron (assuming uniform radial temperature distribution) and the copper temperature the average of the temperatures of the bottom portion of the top coil side and of the top portion of the bottom coil side, the portions which mainly influence the reading of the detector. From this definition, the required temperature differential is temperature difference, copper to detector$=(1-F)\times$temperature difference, copper to iron. In the derivation of the factor F, in both the mathematical and the calculating board analyses both the tooth iron and the top and bottom coil sides were assumed to be at uni-

form temperatures. Actually, the radial temperature distribution in the coil sides and the tooth is nonuniform, as shown by Figs. 6 and 7. However, since the reading of the temperature detector is influenced mainly by the copper temperatures in the bottom portion of the top coil side and in the top portion of the bottom coil side and, since the average of these two temperatures was in most of the cases analyzed not greatly different from the average of the mean temperatures of the two coil-sides, the factor F can be equally well defined with reference to the latter temperature. The assumption of a uniform tooth temperature may likewise be justified, by reference to Fig. 6.

The factor F is mainly a function of the following design parameters (See Fig. 4.):

1. Thickness of coil side insulation, b (includes slot clearance space).
2. Ratio, b/b_1
$$=\frac{\text{side insulation thickness}}{\text{total width of copper in slot}}$$
3. Ratio, $\alpha=b_2/b$
$$=\frac{\text{radial distance from edge of copper to center of detector}}{\text{side insulation thickness}}$$
4. Thermal resistivity of side ground insulation, ρ_t.
5. Ratio, $\gamma=$
$$\frac{\text{transverse thermal resistivity of insulation } \rho_t}{\text{longitudinal thermal resistivity of insulation}}$$
(See Fig. 10).
6. Outer radius of coil corners, r.
7. Radial temperature distribution in top and bottom coil sides.
8. Thermal resistivity of temperature detector material, ρ_D.
9. Amount of ventilation of temperature detector.

The method of evaluating the factor F for the various design parameters, by use of the d-c calculating board, is described in Appendix II. The results of the analysis are contained in the following.

Values of Factor F for Coils with Corner Radius r=0

With the use of the network illustrated in Fig. 11, values of the factor F were obtained from the calculating-board analysis for several values of b/b_1, α and γ, for the following conditions:

1. $\rho_D=150$ C, inches per watt
2. $\rho_D=\infty$

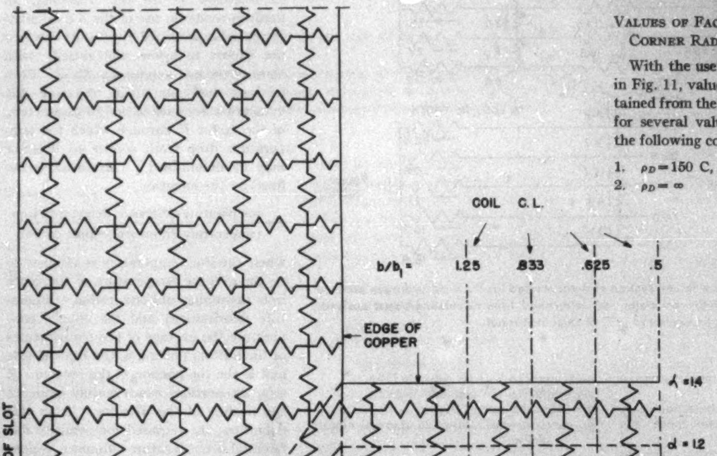

Fig. 11. Representation of top armature bar insulation and adjacent embedded temperature detector by a network of thermal resistors for use in calculating-board analysis of temperature difference, copper to detector. For outer coil radius r=0. Dimensional ratios b/b₁ and α variable. For b/b₁ < 0.5, network is extended to right

The results of this analysis for $\alpha=1$ and $\gamma=1$ to $\gamma=8$, for condition 2, are shown in Fig. 12. The values determined for condition 2 from the mathematical analysis[4] for $\alpha=1$ and $\gamma=4$, 5, and 6, are shown for comparison and are observed to be slightly higher than the values obtained from the calculating-board analysis.

Figs. 13 and 1 give values of the factor F as determined from the calculating board analysis for conditions 1 and 2 for various values of b/b_1, α, and γ, with values from reference[4] for condition 2 shown for comparison. Substantial agreement is shown between the values of F determined from the calculating-board study and the values from the mathematical analysis. Placing the temperature detector in the thermal circuit, (i.e., changing its thermal resistivity from ∞ to 150 C in per watt) is shown to reduce the calculated value of F by a small amount.

VALUES OF FACTOR F FOR COILS WITH OUTER CORNER RADIUS, $r \neq 0$ AND FOR UNEQUAL COIL SIDE TEMPERATURES

In representing these conditions on the calculating board, an outer coil radius of $r=0.14$ inch was assumed, and a thermal network representing the coil insulation for the two coil sides was used. Also, calculations were made for the following conditions:

1. The space bounded by outer corner surface, slot wall and detector sealed with a packing.
2. Corner packing omitted and the exposed coil and detector surfaces maintained at the temperature of the slot wall.

Condition 2 corresponds to an intensive ventilation of the temperature detector.

Fig. 2 gives values of F for various values of b/b_1 and γ as determined from the calculating-board analysis for $\alpha=1$ and $T_1/T_2=1$ (where T_1 and T_2 are the temperature rises of top and bottom coil sides above iron temperature respectively) for coils with $r=0.14$ with corner space packed, with values of F determined for coils with $r=0$ shown for comparison. A small increase in the value of F resulting from the rounding of the coil corners is indicated.

Fig. 3 shows the effect on the value of F of an intensive ventilation of the temperature detector, also of varying the ratio T_1/T_2 from 1.0 to 1.45, as determined from a calculating-board analysis for $\alpha=1$, $\gamma=5$. It is shown that the value of F increases slightly as the ratio T_1/T_2 is increased, and that intensive ventilation of the coil corner and of the detector edges reduces the value of F by several per cent.

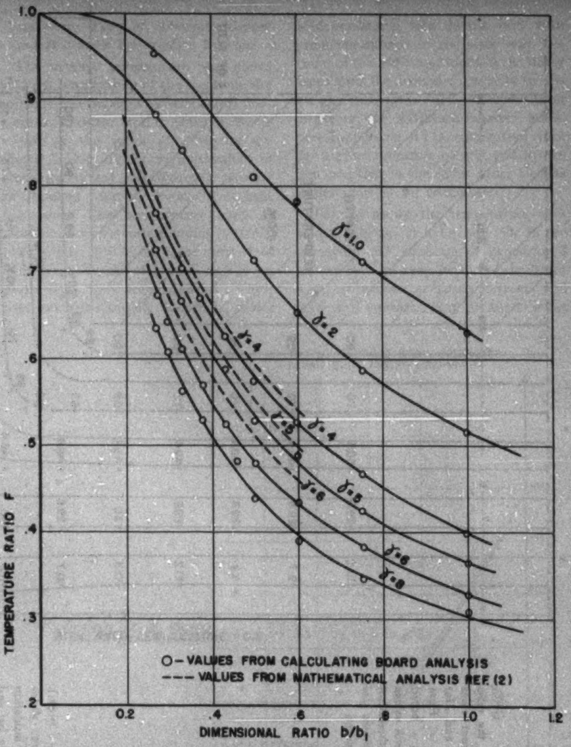

Fig. 12. Values of the ratio F for different values of b/b_1 and γ, for $\alpha=1$. For $r=0$, $\rho_D=\infty$. From calculating-board analysis, with values from mathematical analysis shown for comparison

TEMPERATURE DISTRIBUTION IN COIL INSULATION AND DETECTOR

The temperature distribution in the coil insulation and along the width of the temperature detector as determined from a calculation-board analysis for a coil with rounded corners, with corner packing provided, for assigned values of α, γ, b/b_1, and T_1/T_2 is shown in Fig. 14. In Fig. 15 the radial temperature distribution in the coil insulation along the slot centerline has been plotted, as has the temperature distribution along the detector width, for the same values of the several design parameters as in the foregoing. This has been done for corner packing provided, and for corner packing omitted, detector ventilated. From the temperature curves shown at the bottom of Fig. 15 it may be deduced that the temperature-detector element is sufficiently narrow in width (0.09 inch) to read the peak of the temperature curve, which is on the slot centerline. From the upper curves in Fig. 15 it is shown that the temperature gradient in the insulation on the radial slot centerline is nonlinear.

RESULTS

The significant points from the foregoing analysis may be summarized as follows:

1. For the condition of the coil outer corner radii = 0, the values of the factor F obtained from the calculating-board analysis were in substantial agreement with those obtained from the mathematical analysis.
2. If adequate packing of the coil corners is provided so that the effect of detector ventilation on the detector reading may be neglected, the curves given in Fig. 1 may be used with fair accuracy to predict the

4. Factory Tests on Four Generators

During the past 2 years, factory heat run tests have been conducted on four 3,600-rpm hydrogen-cooled generators provided with thermocouples on the copper of the armature bars, by means of which the copper temperatures in operation at various currents and at various hydrogen pressures were determined. The ratings of the four generators (at 1/2-psi hydrogen pressure) were as follows:

Generator no. 1,	18.75 mva,	0.80 pf,	13.8 kv
Generator no. 2,	100 mva,	0.85 pf,	14.4 kv
Generator no. 3,	105.8 mva,	0.85 pf,	14.4 kv
Generator no. 4,	129 mva,	0.85 pf,	20 kv

Generator no. 1 was tested at rated pf on the load test stand at one of the General Electric plants; the other three generators were each tested under conditions of zero excitation, open circuit and short circuit.

TEST ARRANGEMENT

A diagram showing the locations of the various temperature-detecting devices employed in the tests on generator 4 is given in Fig. 16. Similar arrangements were provided for the tests on the other three generators, although the ventilating-circuit arrangements varied among the machines. The thermocouples on the armature-winding copper were located on three top neutral bars at several stations along the length of the stator, the thermocouples in each group being spaced about 2 inches apart axially, and positioned radially as shown in the inset in Fig. 16. Thermocouples molded into strips of laminac, and resistance temperature detectors attached to specially designed slot wedges, were provided for measuring temperatures in the air gap. Tooth iron temperatures were measured with thermocouples located on the axial center line and at the outer edges of the iron packages, at about one-third of the way up the tooth from the tip.

TEST RESULTS

The principal results of the tests on the four generators are summarized in Figs. 17 to 24. These results are briefly discussed in the following.

Temperature Rises of Armature Copper and Resistance Temperature Detectors

The average temperature rises above cold gas temperature of the top armature coil-side and the adjacent embedded temperature detector, in the center discharge section of the stator of generator are shown in Fig. 17 for various values of armature current and hydrogen pressure as obtained from the short-circuit heat run tests. The temperature rises at armature currents corresponding to 100%, 115%, and 125% of the rated current, at hydrogen pressures of 1/2, 15 and 30 psi respectively, have been indicated. These rises are substantially less than under load conditions, and do not vary with armature current in the same way, because of the additional losses in the stator teeth and the increased gas rise in the air gap from rotor I^2R losses under load. However, the difference between armature copper and RTD temperature rises, for a given armature current and hydrogen pressure, is the same under load as under short-circuit conditions.

Fig. 18 shows the temperature rises above cold gas of a top coil side in the armature end windings of generator 3 at two stations near the end of the stator core, at various armature currents and hydrogen pressures, from the short-circuit

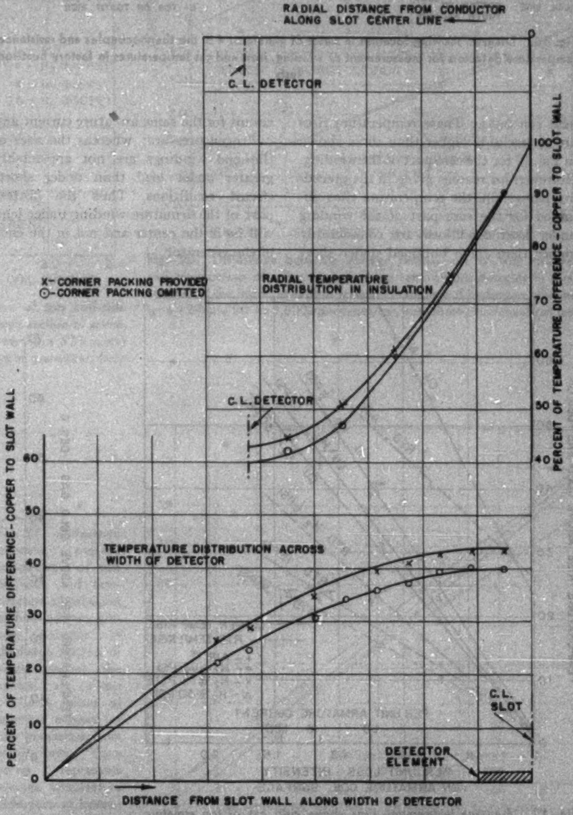

Fig. 15. Temperature distribution in armature bar insulation along radial slot center line, and across width of temperature detector, for $r = 0.14$ inch, $b/b_1 = 0.625$, $\alpha = 1$, $\gamma = 5$, $T_1/T_2 = 1$, $\rho_D = 150$ C inch per watt; for corner packing provided; and for corner packing omitted, exposed bar corner and detector surfaces at iron temperature. From calculating-board analysis

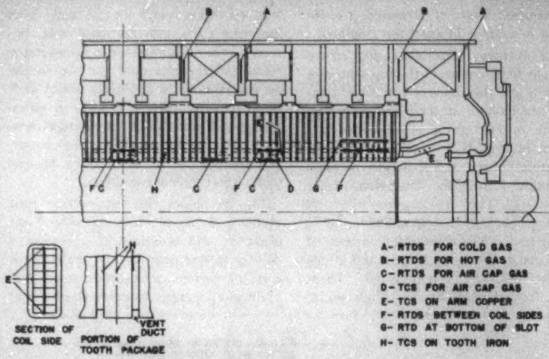

Fig. 16. Diagram showing location in stator of generator 4 of the thermocouples and resistance temperature detectors for measurement of winding, iron and gas temperatures in factory heat-run tests

heat run tests. These temperature rises are appreciably higher than those shown in Fig. 17 for the core part of the winding. However, for reasons given in the preceding paragraph, the temperature rises obtained for the core part of the winding under load conditions are considerably higher than those obtained under short circuit for the same armature current and hydrogen pressure; whereas the rises of the end windings are not appreciably greater under load than under short-circuit conditions. Thus the hottest part of the armature winding under load will be in the center and not in the ends of the generator.

Temperature Drop Through Armature Bar Insulation

The temperature drop from the average copper temperature in the top armature coil side to the average tooth iron temperature, representing the thermal drop in the top bar insulation, is shown in Fig. 19 as obtained from short-circuit heat runs on generators 3 and 4 at various armature currents and hydrogen pressures, from measurements made in the center discharge section of the core. This temperature drop is shown to be independent of the hydrogen pressure. With the use of the calculated a-c I^2R loss in the top bar, and assuming a division of losses to tooth and vent duct as calculated using the equations (given in the section "Theoretical Analysis of Armature Temperatures," paragraph 4) the thermal resistivities of the top bar insulation for the two generators were determined to be 110 and 127% respectively, of the value for bar insulation of maximum density as determined by laboratory tests. For generators 1 and 2 the thermal resistivities of the top bar insulation were similarly found to be 107 and 130% respectively, of the latter value. (In calculating the insulation thermal resistivity for generators 2 and 4, an axial heat flow in the top bar equal to 5% of the generated loss was assumed, as estimated from the curves of axial tem-

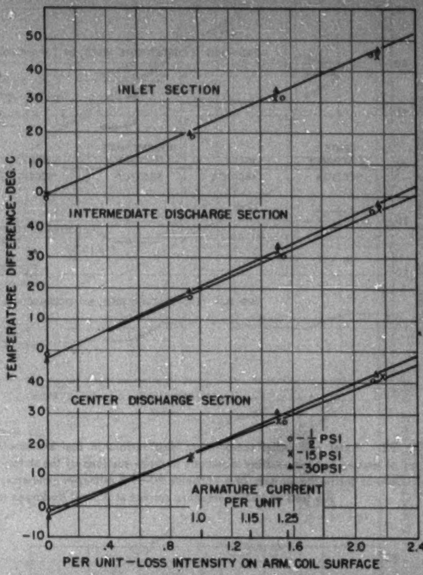

Fig. 20. Difference between average temperature of top coil-side and temperature of adjacent embedded temperature detector in three sections of the stator, at various armature currents and hydrogen pressures for a 129-mva 20-kv 3,600-rpm generator, from short-circuit heat-run tests

perature distribution determined from the tests; see Fig. 22. For generators 1 and 3 the test curves of temperature distribution indicated negligible axial heat flow, hence none was assumed in calculating the insulation resistivity.)

Temperature Drop from Average Top Bar Temperature to Temperature Detector

The differential between average top bar temperature to temperature detector is shown in Fig. 20, as measured in three sections of the stator of generator 4 at various armature currents and hydrogen pressures. It is shown to be practically the same in all sections, for the same armature current, indicating little variation in the bar conditions in different parts of the stator. Also, the drop appears to be little influenced by changes in the hydrogen pressure, indicating negligible ventilation of the temperature detector. (All four generators showed this same result.) The small negative temperature differential obtained at zero arma-

ture current, which was obtained for generators 1 and 4, but not significantly for generators 2 and 3, is caused by the heat flow from iron to copper due to windage and tooth iron losses. In Fig. 21 the difference between average top bar temperature and the detector temperature as measured in the core discharge section nearest the center of the generator is shown for all four generators for different per-unit armature currents. The curves given represent average values of this temperature difference for the different hydrogen pressures at which the tests were made; although, as previously noted, the measured drop was substantially independent of the gas pressure. The variation in this temperature drop among the four generators, between average and maximum, for the same per-unit armature current is about 8%.

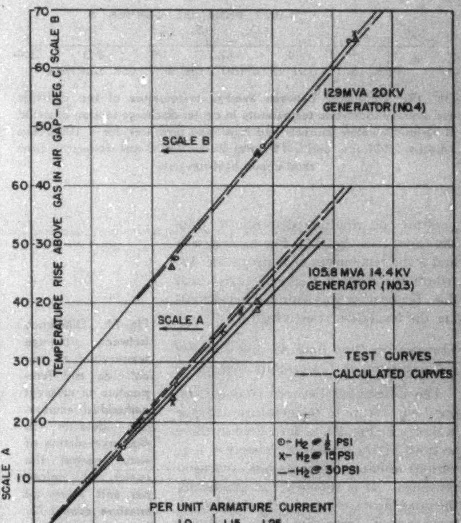

Fig. 24. Average temperature rise of top armature coil-side above gas temperature in air gap opposite center stator discharge section, at various armature currents and hydrogen pressures, for a 105.8-mva 14.4-kv 3,600-rpm and a 129-mva 20-kv 3,600-rpm generator, from short-circuit heat-run tests, with temperature rises calculated from equations shown for comparison in section 2 ("Equivalent Thermal Circuit")

gap temperature along the gap for generator 4, as determined from a short-circuit heat run test at 125% armature current at 1/2-psi hydrogen pressure. The radial temperature distribution in the top bar is shown to agree, essentially, with the curves shown in Figs. 6 and 7, as obtained from the calculating board analysis on the 111-mva, 13.8-kv generators, the highest copper temperature occurring about halfway up the coil side, and the temperature of the top strand of the bar being somewhat higher than that of the bottom strand. In calculating the average coil-side temperatures from the thermocouple readings, parabolic temperature distribution in the coil side radially was assumed. Under this assumption, the difference between maximum and average bar temperatures was in most cases only a few degrees C, hence the curves of temperature differential between copper and temperature detector given in Fig. 21 may be used without significant error, to predict from the detector readings the hot spot as well as the average temperature of the top coil side.

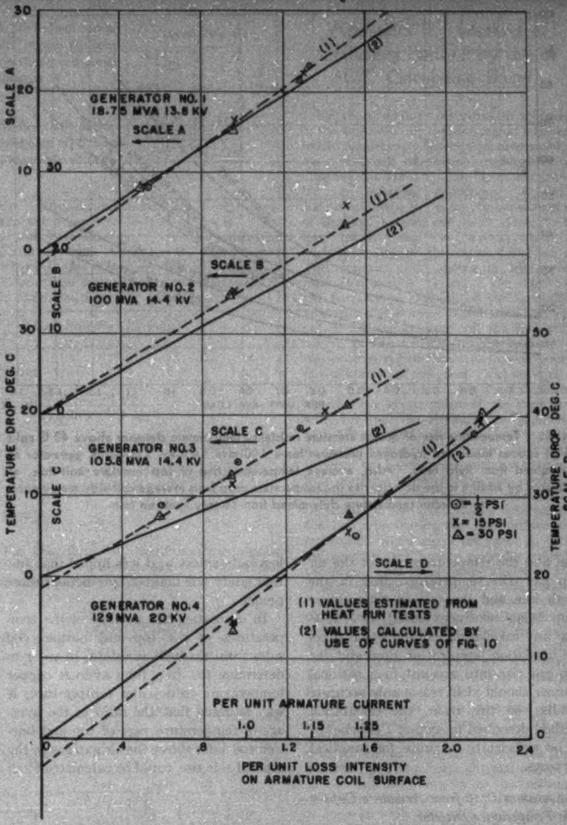

Fig. 25. Difference between average of temperatures of top and bottom coil-sides and temperature of embedded detector, in stator discharge section nearest center of generator at various armature currents and hydrogen pressures

1—As estimated from heat-run tests, using a calculated ratio of average coil-side temperature to top coil-side temperature

2—As calculated by use of the curves of Fig. 1 using values of insulation thermal resistivity determined from the tests

Air-Gap Temperatures

Fig. 23 shows the average temperature rise of the gas in the air gap at three stations axially along the generator for generator 3 at various armature currents and hydrogen pressures, as obtained from the short-circuit heat run tests. The gap gas temperature rise at the center of the generator, which represents the ambient gas rise for the hottest section of the armature winding, is shown to be appreciably higher than the total gas rise through the generator, at all gas pressures. This is caused by the temperature rise from the rotor I^2R loss, of the rotor ventilating gas which is discharged into the air gap at the center of the generator. Similar results were obtained in the tests on generators 2 and 4. For generator 1 the center ventilation section of the stator core was an inlet instead of an outlet section, as it was for the other generators, so that a different axial distribution of gap gas temperatures was obtained.

Analysis of Tests

Temperature Rise of Armature-Winding Copper

As an approximate check on the accuracy of the calculation method described in section 1 the average temperature rise of the top armature bar above air gap temperature was calculated by this method for the four generators tested, and for different armature currents and hydrogen pressures. These were compared with the temperature rises obtained from the heat run tests. Fig. 24 gives these calculated temperature rises for generators 3 and 4, with test values for the center discharge section shown for comparison. The good agreement shown between test and calculated copper temperature rises, while gratifying, should not be taken as complete proof of the accuracy of the calculation method; for, since the values of insulation thermal resistivity used in the calculations were estimated from the heat run data and, since the temperature drop in the bar insulation comprises about 90% of the copper rise above the air gap temperature, substantial agreement between test and calculated values was to be expected. However, since we are interested primarily in the temperature rise of the armature-winding copper above cold gas, and since the main components of this rise are the temperature drop in the coil-side insula-

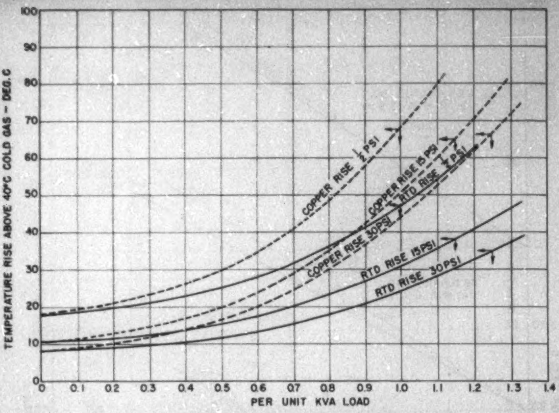

Fig. 26. Temperature rise of hottest armature resistance temperature detector above 40 C cold gas at various loads and hydrogen pressures for a 100-mva 14.4-kv 3,600-rpm generator as determined from field tests. Also, average temperature rise of top armature coil-side, as estimated by adding to the detector rise the temperature drop from average coil-side temperature to detector temperature determined from factory heat-run tests

tion and the temperature rise of the air gap gas (the temperature drop in the tooth iron and the surface temperature drop being relatively small), it follows that any calculation method which takes the insulation temperature drop and the gap gas rise into account in a rational manner should yield reasonably accurate results; on this basis, the calculation method described in section 1 is believed to be sufficiently accurate for practical purposes.

Temperature Drop from Armature Copper to Temperature Detector

To provide an approximate check on the validity of the analysis given in section 2, the temperature drop from the average temperature of top and bottom armature bars to the detector temperature was calculated for various armature currents for the four generators tested, by use of the *F* factor given by the curves of Fig. 1, using the values of insulation thermal resistivity determined from the tests, and compared with the values of this temperature drop estimated from the tests.

This comparison is given by the curves of Fig. 25. For generators 1, 2, and 4 the agreement between the values of temperature difference estimated by the use of the *F* factor given by the curves of Fig. 1, and the values estimated from the heat run data, may be considered satisfactory. However, for generator 3 the agreement is less satisfactory and it is hoped that further study will make all predictions more precise.

In estimating the average of the temperatures of the top and bottom coil sides from the heat run data, in order to determine the drop from average copper temperature to detector temperature, it was assumed that the ratio of the average of temperature rises of top and bottom coil sides above the air gap gas to the top coil side rise, could be calculated from the equations given in section 2 ("Equivalent Thermal Circuit"). This assumption was necessary since the temperature of the bottom coil side was not measured in the tests. The ratio was in most cases approximately 0.9. It was also assumed in the calculations that the thermal resistivity of the coil side insulation was the same for both top and bottom coil sides. However, even under the limitation of these assumptions it is indicated that the analysis given in section 2, when properly calibrated by tests, provides a satisfactory basis for determining the temperature of the armature-winding copper from readings of the temperature detector.

5. Field Tests on Two Generators

The temperature rises of the armature copper and temperature detectors were determined for generator under 1 actual load conditions from the factory tests. However, the other three generators, having been tested in the factory under zero excitation, under open- and short-circuit conditions only, required testing in the field to determine the armature heating under load conditions. Figs. 26 and 27 give load test data on generators 2 and 4 as obtained from field tests. Fig. 26 gives the temperature rises of the hottest armature temperature detector above 40 C cold gas at various loads at rated pf for generator 2. To the values of temperature detector rise obtained in the load tests, the pertinent values of temperature drop from average top coil-side temperature to detector temperature obtained in the factory tests (refer to Fig.

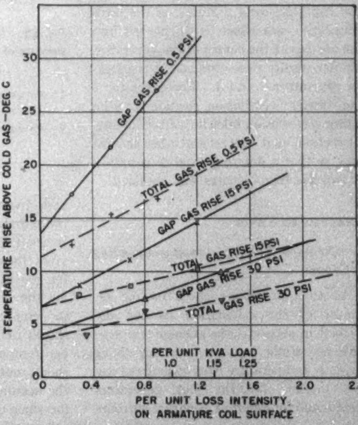

Fig. 27. Average temperature rise of gas in air gap opposite center stator discharge section, at various loads and hydrogen pressures, for a 120-mva 20-kv 3,600-rpm generator, as determined from field tests

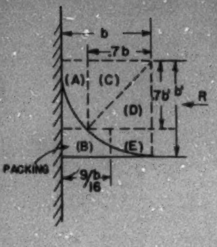

Fig. 28 (left). Division of corner insulation into several sections for calculation of corner thermal resistance R

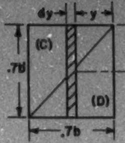

Fig. 29 (right). Calculation of thermal resistance of section (CD) of corner insulation

21) were added, giving the curves of average temperature rise of top coil side versus load shown in Fig. 26. It is observed that for the specified generator capabilities of 115% at 15 psi and 125% at 30 psi the copper temperature rises are slightly under the values estimated for rated load 1/2 psi. Considering the usual increases in cold gas temperature over 40 C obtained at these elevated loads and gas pressures, of from 4 to 6 C, the hot-spot armature-winding temperatures for these overload conditions would for this generator be only slightly higher than at rated load 1/2-psi pressure.

Fig. 27 gives curves of average temperature rise of the gas at the center of the air gap for generator 4 as determined from field tests at various loads at rated pf, and at different hydrogen pressures. Comparison of these curves with those given in Fig. 23 as obtained from factory tests at short circuit for generator 3 indicates nearly the same relationship between gap gas rise and total gas rise, except that the difference between the two rises is considerably greater under load than under short-circuit conditions, because of the increased rise of the rotor ventilating gas which discharges into the center of the air gap, from the field I^2R loss.

Appendix I. Calculation of Armature Bar Corner Resistance R

In the calculating-board analysis of the armature copper temperatures, calculation of the thermal resistance of the insulation in the corner of the armature bar is required. In the corner, referring to Fig. 10, the heat from the coil side flows both along the mica laminations and across them; also the space between the outside of the insulation, the tooth, and the detector, is sealed with packing to prevent ventilation of the temperature detector; hence the calculation of the corner resistance R is a rather complex problem.

For the resistance calculation, the corner insulation was considered to be divided into several resistances, as shown in Fig. 28. Assuming parallel lines of heat flow through the corner, the resistances ($R_A \ldots R_E$) were evaluated for the designated areas. The actual heat flow lines will be somewhat distorted from the assumed flow lines; however, this distortion will be neglected. From these assumptions, the resistance R is calculated from the equation

$$R=\frac{(R_A+R_C+R_D)(R_B+R_E)}{R_A+R_B+R_C+R_D+R_E}$$

where

$$R_A=\frac{(0.3b)\rho_t}{X_t(0.7b')}=\frac{3}{7}\,\frac{b\rho_t}{b'X_t}$$

$$R_B=\frac{9}{16}\,\frac{b\rho_t}{X_t(0.3b')}$$ (Assuming thermal resistance for material in corner space the same as for coil)

$$R_E=\frac{7}{16}\,\frac{b\rho_t}{X_t(0.3b')\gamma}$$

The heat flow will divide between regions C and D. Considering a differential element, as in Fig. 29

$$d(R_C+R_D)=\frac{\dfrac{(\rho_t dy)}{(xX_t)}\,\dfrac{(\rho_t dy)}{(\gamma X_t)(0.7b'-x)}}{\dfrac{\rho_t dy}{xX_t}+\dfrac{\rho_t dy}{\gamma X_t(0.7b'-x)}}$$

$$=\frac{b\rho_t}{X_t b'(\gamma-1)}\,\frac{dy}{\dfrac{(0.7b\gamma-y)}{(\gamma-1)}}$$

therefore

$$R_C\pm R_D=\frac{b\rho_t}{b'X_t(\gamma-1)}\int_0^{0.7b}\frac{dy}{\left(\dfrac{0.7b\gamma}{\gamma-1}\right)-y}$$

$$=\left(\frac{l_n\gamma}{\gamma-1}\right)\left(\frac{b\rho_t}{X_t b'}\right)$$

Note that as $\gamma \to 1.0$ denoting equal transverse and lengthwise resistivities

$$R_C+R_D\to\left(\frac{b\rho_t}{X_t b'}\right)$$

which is as it should be.

Evaluating R for $\gamma=4.0$ results in

$$R=0.611\,\frac{b\rho_t}{X_t b'}$$

A calculating-board study (obtained by breaking the corner up into small sections and including the proper resistivity of the corner packing) showed

$$R=0.650\,\frac{b\rho_t}{X_t b'}$$ for 100-megawatt generator

$$R=0.720\,\frac{b\rho_t}{X_t b'}$$ for 111-megawatt generator

which were quite reasonable checks on the method of calculation.

Appendix II. Method of Evaluating Factor F by Use of D-C Calculating Board

By the procedure described in reference 5, the insulation in the slot region adjacent to the temperature detector was represented by a network of thermal resistances, as illustrated in Fig. 11. The latter was drawn for the following conditions: 1. outer coil radius, $r=0$; 2. equal temperature rises of top and bottom coil sides above tooth iron temperature, i.e., $T_1=T_2$; and 3. various values of the ratios b/b_1 and α. The diagonal lines shown in the corner insulation in Fig. 11 locate the planes of the surfaces of division of the insulation into side and bottom regions; in the side region the laminations of the insulation course in the vertical direction, while in the bottom region the laminations course in the horizontal direction. The network of Fig. 11 was set up on the d-c calculating board for a given value of the ratio b/b_1 with the resistors adjusted in accordance with the specified values of α and γ. With a given potential difference maintained between the busses representing copper and iron surfaces respectively, the potential difference between the point representing the center of the temperature detector and the bus representing the iron surface was measured. The ratio of the latter potential difference to the former gave the value of the ratio F, for the assumed values of b/b_1, α and γ. For evaluation of the ratio F for unequal temperatures of top and bottom coil sides, a network representing the coil insulation for both coil sides was used, while for the condition of outer coil radius $r\neq 0$ the corner insulation was represented by a network of resistors arranged in curvilinear squares.

The resistances of the resistors of the thermal network illustrated in Fig. 11 were evaluated for unit thickness of the insulation perpendicular to the plane of the page. Denoting the transverse thermal resistivity of the coil insulation by ρ_t the resistance of a unit resistor for transverse heat flow is $R_X=\rho_t$, while that of a unit resistor for a longitudinal heat flow is $R_y=\rho_t/\gamma$. At the iron and copper boundaries, except at the corners, the resistances of the resistors are one-half the above values. For the resistors representing the region adjacent to the corner diagonals, the resistances were calculated as follows: From Appendix I, the thermal resistance of a block of insulation of unit depth in which the direction of the laminations on either side of a diagonal plane across the corners of the block differs by 90 degrees is given by the equation

$$R_{CD}=AB \tag{1}$$

where

$$A=\frac{l_n\gamma}{\gamma-1} \tag{2}$$

and

$$B=d/w \tag{3}$$

where

d = length in block in direction of heat flow
w = width of block

For

$\alpha = 1$

for which the resistances are symmetrical on either side of the diagonal, i.e., $B = 1$, the resistance of resistor *a* in Fig. 11 can be readily shown to be

$$R = (\rho_i/\gamma)\left[0.5 + \frac{A}{A+1/\gamma}\right] \tag{4}$$

while the resistance of resistor *b* can be shown as

$$R = \rho_i\left[0.5 + \frac{A}{1+A}\right] \tag{5}$$

The resistance of the corner resistors *C* and *d* in Fig. 11 is given by the equation

$$R_c = R_d = \frac{A\rho_i}{1+A} \tag{6}$$

The resistances of the unit resistors of the temperature detector are given by the equation

$$R_D = \rho_D L_D / W_D \tag{7}$$

where

L_D = length of unit resistor of detector
W_D = width of unit resistor of detector
ρ_D = thermal resistivity of detector material

For values of $\alpha \neq 1$, the resistors adjacent to the diagonals do not have symmetrical resistance values on either side of the diagonal, i.e., $B \neq 1$. For this condition, the resistances R_a, R_b, etc., are calculated in the same manner as for $\alpha = 1$, first calculating R_{CD} from equation 1, and then combining this resistance in series parallel with the resistances of the other sections of the block of insulation represented by the resistor.

Discussion

M. D. Ross (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors have mentioned the recommendations of the Synchronous Subcommittee of the ASA C-50 group in regard to standard ambient temperatures. The following discussion outlines the basis for the recommended values.

When the first hydrogen-cooled turbine generators were designed, the gas-tight structure and the coolers were arranged for a maximum of 0.5-psi hydrogen pressure. A few years later, there was a demand for higher gas pressures, and a large number of machines were built with a capability rating at 15 psi. Within the last 7 years, a number of generators have been sold to operate up to a maximum hydrogen pressure of 30 psi. In all these designs, the gas coolers were arranged for an outlet gas temperature of 40 C at the half-pound maximum rating and with the specified maximum water temperature and flow. The temperatures obtaining at the outlet of the cooler with 15 psi and later with 30 psi were determined by the half-pound condition. These temperatures at the outlet of the cooler will vary somewhat with the design of the generator and the relative losses at the capability ratings. The variation may be as much as 6 C between the half-pound condition and the 30-psi condition.

It is entirely normal for the ambient temperature of hydrogen-cooled machines to increase over 40 C when the machine is operated at loads and gas pressures higher than the basic rating at 0.5 psi, but this phenomenon is not understood by many operators. It may be explained as follows.

When a machine is operated at gas pressures over 0.5 psi with correspondingly higher loads, the increase in losses in the machine is almost exactly balanced by the increase in heat transfer capability of hydrogen coolers. Therefore, the difference between the average cooler water temperature and the average hydrogen remains approximately constant. However, the ability of the hydrogen gas to absorb heat increases much faster than the losses in the machine for any given increase in gas pressure, with the result that the temperature rise of the gas decreases with increasing gas pressure. Since the average temperature of the gas must remain constant, the reduction in the gas temperature rise results in an increase in cold gas temperature, and a decrease in hot gas temperature at higher gas pressures. Fig. 30 shows the general nature of this phenomenon.

It would require coolers of nearly double the usual size to maintain a 40 C ambient at the 30-psi rating. This would increase the diameter of large machines unreasonably with no extra advantage to the operator, since present temperatures are satisfactory.

It is apparent from this discussion that the characteristics of the gas coolers now in use are quite well matched to the machines with which they are associated. While the gas temperature goes up as the higher gas pressures and capabilities, the machine internal temperatures come down to compensate for the rise in the gas pressure.

The maximum cold gas rises of 40, 44 and 46 C for 0.5, 15 and 30 psig as given in the Committee recommendations clarifies the matter of expected cooler performance with varying gas pressure.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): It is gratifying to see the results of the extensive investigations and studies given in this paper.

In a previous discussion, I raised a question as to the magnitude of the temperature drop between the resistance temperature detector and the armature conductor at a hydrogen pressure of 0.5 psi. More importantly, emphasis was given to using the temperature rise and the total temperature of the armature conductor itself, as the criteria in determining design and operating limits for an armature at various hydrogen pressures. This practice of considering hottest spot temperature or temperature rise as the final criterion is generally used for transformers, cables, contacts of breakers, etc.

It is good to see the very close check between calculations and test results for three of the four generators covered in Fig. 25. The results of the further investigations mentioned will be of interest.

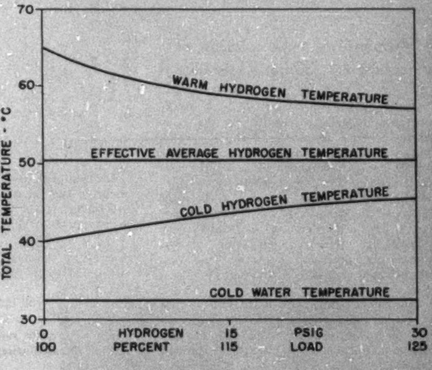

Fig. 30. In a typical hydrogen-cooled generator of conventional design, the cold gas temperature varies as shown

As a result of various discussions with generator manufacturers, I have been using a value of 20 to 25 C as the temperature drop through the armature coil insulation to the resistance detector for a hydrogen pressure of 0.5 psi. For loads in amperes over the name-plate half-pound rating, the temperature drop has been assumed to be proportional to the ratio of the heat at the increased load to the heat in armature conductor at the half-pound rating. Such data as that in Fig. 26 indicate that all these practices in Chicago have been conservative.

The implications of the discussions and data in the article are that designs of armatures are aimed at having hottest-spot copper temperatures of about 115 C or less, assuming inlet hydrogen at the proposed standard values of 40 C with 0.5 psig pressure, etc. It would be of interest to have the authors' comments on loading armatures during, say, ten 1-day summer emergencies each year to currents that would cause increases of about 10 degrees above the hottest-spot temperatures at maximum rated conditions. Also, would their analysis pertaining to this question be modified in case the inlet hydrogen temperatures are held 10 degrees below the proposed ASA range of maximum values of 40 to 46 degrees? Likewise, comments would be appreciated on loading an armature once a year during an emergency some 15 or 20 degrees above the design's hottest-spot temperature at maximum rated load, provided the resulting temperature is not over 130 C.

Regarding the proposed revision of ASA C50 standard, the term "capability" (or "capabilities") is used in notes 2, 3, and 4 of Table Ia and in section 1. It seems to me that in covering, in a commercial transaction, the expected performance of a generator for certain specified currents kilowatts, etc., and conditions, only such terms as "rating," "capacity," and "maximum rating" should be used, and the term "capability" reserved for use by the operator in determining the maximum allowable loading for a given piece of apparatus, after taking into account its particular inherent characteristics, load cycle, installation conditions, and required reliability. These remarks apply to transformers, cables, etc., as well as to generators.

J. R. M. Alger, C. E. Kilbourne, and **D. S. Snell:** The authors thank Mr. Ross for his helpful discussion, which presents a clear explanation of the reason for the increase in cold gas temperature of a generator which occurs with increasing hydrogen pressure and load, a circumstance which is not generally understood by the average operator. The authors also appreciate the comments by Mr. Halperin, which indicate general agreement with the conclusions of the paper. As Mr. Halperin suggests, a figure of approximately 115 C has been accepted by the authors as the maximum allowable hot-spot temperature in operation with cold gas temperatures of 40 to 46 C at hydrogen pressures over the specified pressure range. It is desirable that this temperature should not be exceeded, even for brief periods of operation. However, if system conditions require maximum loading, it must be realized that this operation will reduce the life expectancy of the insulation.

In operation with cold gas temperature below the proposed ASA range of maximum values (40 to 46 C) the load should be held to those values which will ensure that the hot-spot temperature rise does not exceed the rises for normal load conditions, otherwise the differential expansions of the armature coils with respect to the iron will exceed those obtained at the loads corresponding to the capabilities at the various hydrogen pressures, which will in turn reduce the life expectancy of the insulation. That is to say, the generator should be operated at all times in accordance with the capability curves of the generator, and not by endeavoring to hold constant hot-spot temperature.

Answering Mr. Halperin's comments regarding the term "capability," this term and capacity are used interchangeably in the paper and denote the kva output which may be obtained continuously at hydrogen pressures over that for which the rating is determined, for approximately the same or lower hot-spot temperatures and temperature rises. The generator capability is usually the same as the turbine capability, which is the continuous output at generator terminals when the turbine is clean and operating under specified throttle steam and temperature and exhaust pressure with full extraction from all extraction openings.

Oil Flow and Pressure Calculations for Pipe-Type Cable Systems

AIEE COMMITTEE REPORT

THE components of oil-filled cable systems are subject to thermal expansion or contraction in varying degrees; hence as the temperature of these components change with change in load, oil must flow out of or into the system if the desired oil pressure is to be maintained. Solutions for the pressure differentials thus resulting in the case of low-pressure oil-filled cables (Pirelli type) have been presented by Miller,[1] Shanklin and Buller,[2] Miller and Wollaston,[3] and Wollaston.[4]

Similar problems are encountered in high-pressure oil-filled pipe-type cable installations where it is desirable to know the maximum oil pressures which may be developed on sudden application of load, and the size of the pump and the pumping pressures which must be provided in order to maintain a minimum pressure at any point in the line when load is dropped. The solutions of these and related problems are presented in this report.

General Considerations

The pressure differentials under consideration depend upon the oil demand or the rate of change of oil content per foot of pipe. This change in oil content is dependent not only upon the expansion or contraction of the oil itself with change in temperature, but also upon corresponding volumetric changes with temperature in the conductor, insulation, and pipe. Because of the different thermal characteristics of the mediums involved, the temperature will vary discontinuously from the conductor to pipe.

Unlike the low-pressure oil-filled cable where the oil demand of the insulation, which contains the larger portion of the oil, may be determined as a mathematical function, a practical solution of the pipe cable involves dividing the system into a number of zones for each of which the average rate of temperature change with time must be determined in some manner. The zones established are the conductor, insulation, free oil space, and the pipe.

The greatest part of the thermal expansion or contraction will occur in the free oil zone through which the major portion of the heat flow is carried by thermal convection. As indicated in reference 5, the thermal drop resulting from this mode of heat transfer is concentrated in thin films at the boundary surfaces, hence the body of oil will be at substantially a uniform temperature. Actually, therefore, this method of treating the oil space is not a simplification but the best method of representation.

Paper 55-32, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 16, 1954.

The personnel of the Working Group on Pipe-Type Cable Hydraulics of the AIEE Committee on Insulated Conductors are: J. H. Neher, *Chairman*, F. H. Buller, R. W. Burrell, G. N. Everest, B. J. Merrell, M. H. McGrath, M. Morris, and J. C. Parker.

Nomenclature

a = oil demand due to conductor loss, cubic inches per foot per second
a_d = oil demand due to dielectric loss, cubic inches per foot per second
B = flow resistance, pound-seconds per square inch per cubic inch per foot
c = circumference of an area, inches
D_b = diameter of by-pass piping, inches
D_c = diameter of conductor, inches
D_i = diameter oven insulation, inches
D_0 = inside diameter of pipe, inches
D_p = outside diameter of pipe, inches
D_s = diameter over shielding tapes, inches
E_s = modulus of elasticity of steel, pounds per square inch (psi)
E_0 = bulk modulus of oil, psi
f = shear force per unit area, psi
F = flow rate, cubic inches per second
F_0 = constant flow rate delivered by the pump, cubic inches per second
γ = specific gravity of the oil
h_0 = unit temperature-time transient of the oil, thermal ohm feet, degrees centigrade (C) feet per watt
Δh = change in elevation, feet
H_{ce} = steady-state thermal resistance from conductor to ambient earth, thermal ohm feet
H_{ie} = steady-state thermal resistance from mid-insulation to ambient earth, thermal ohm feet
H_{oe} = steady-state thermal resistance from mid-oil to ambient earth, thermal ohm feet
H_{pe} = steady-state thermal resistance from pipe to ambient earth, thermal ohm feet
K = ratio of pressure drop in the pipe with cables to the pressure drop for the same flow without cables
l = length of a by-pass system, feet
L = length of main pipe, feet
M = inertia in pound square seconds per square inch per cubic inch per foot
μ = viscosity, centipoises
μ_0 = initial viscosity of the oil, centipoises
N = number of by-pass systems associated with main pipe
O_l = oil requirement due to load change, gallons
O_s = oil requirement due to seasonal temperature changes, gallons
P_b = pressure differential in the by-pass systems, psi
P_f = frictional pressure drop, psi
P_h = hydrostatic pressure, psi
P_m = pressure differential in the main pipe, psi
P_0 = constant pressure impressed by the pump, psi
ΔP = elastic transient pressure increment, psi
Q = heat flow resulting from a-c losses in one conductor, watts per foot
Q_d = heat flow resulting from dielectric loss of one cable, watts per foot
s = area, square inches
t = time, seconds
t_0 = time at which load is dropped, seconds
t' = time at which the oil demand is a maximum after dropping load, seconds
τ = unit of time (Appendix II)
T_c = conductor temperature, C
T_i = mid-insulation temperature, C
T_0 = oil temperature, C
T_0' = initial oil temperature, C
ΔT_{0d} = oil temperature change due to dielectric loss, C
T_p = pipe temperature, C
u = flow velocity, inches per second
V = volume, cubic inches per foot
V_e = elastic volume change, cubic inches per foot per pound per square inch
x = distance from the closed end of the line, feet
y = distance from pipe or cable surface, inches

The basic equation for the change in oil volume ΔV in cubic inches per foot with change in temperature for three cables in the pipe is

$$\Delta V=\begin{Bmatrix}0.0060\\0.0036\end{Bmatrix}D_c^2\Delta T_c+0.0120(D_i^2-D_c^2)\Delta T_i+0.0070(D_0^2-3D_s^2)\Delta T_0-0.0003D_p^2\Delta T_p \text{ inches}^3 \text{ per foot} \quad (1)$$

in which ΔT_c, ΔT_i, ΔT_0, and ΔT_p are the temperature changes in C of the conductor, mid-insulation, the oil, and the pipe of outer diameters D_c, D_i, D_0, and D_p in inches respectively; and D_s is the diameter over the shielding tapes. The two constants appearing in the first term apply to concentric stranded or to compact segmental conductors. Equation 1 is based upon the composition of components given in Table I. It will be noted that the last term is negative since the pipe expands on increase in temperature and effectively reduces the change in volume of oil.

If a given load, which has been sustained until steady-state temperatures prevail, is removed from the cable system, the rate at which oil is absorbed per-unit length of the system is known as the oil demand and is commonly indicated as a in cubic inches per foot per second. This quantity is a function of the load dropped and the elapsed time. When a given load is suddenly applied to the system, oil will be ejected from the system at exactly the same rate, and thus the oil demand is most conveniently found by differentiating equation 1 with respect to time

$$a=\frac{d}{dt}\Delta V \text{ inches}^3 \text{ per foot-second} \quad (2)$$

This in turn requires the determination of the temperature rises ΔT_c, ΔT_i, ΔT_0 and ΔT_p as functions of time, which are directly proportional to Q, the heat liberated at each conductor in watts per foot.

The calculation of the corresponding per-unit temperature-time transients at conductor and insulation, oil, and pipe for a particular cable system may be accomplished mathematically as indicated in reference 6. However, this is a time-consuming process and these transients may be determined more readily by use of an analogue computer.[7] This has been done for the six typical pipe-type cable systems outlined in Table II and the resultant per-unit oil demands, a/Q in cubic inches per second per foot of pipe per watt per foot of conductor (cubic inches per watt-second), are shown in Fig. 1. In many cases the per-unit demand may be interpolated from these

Table I. Composition and Coefficients of Expansion of the Several Zones

Material	Coefficient of Expansion	Conductor, Per Cent: Concentric Stranded	Conductor, Per Cent: Compact Segmental	Insulation, Per Cent	Oil, Per Cent	Pipe, Per Cent
Copper	5×10^{-5}	77	79			
Paper	10×10^{-5}		10.5	50		
Oil	75×10^{-5}	23	10.5	50	100	
Steel	3.6×10^{-5}					100
Net coefficient of expansion		21.1×10^{-5},	12.9×10^{-5},	42.5×10^{-5},	75×10^{-5},	3.6×10^{-5}.

Table II. Typical Pipe-Type Cable Systems

System	Voltage	Conductor		Insulation, Mils	Pipe, Inches, Outside Diameter	Q_d, Watts per Foot	D_s/D_0^2
I	69 kv	350, MCM*	concentric stranded	285	$5^9/_{16}$	0.31	0.255
II	138 kv	350, MCM	concentric stranded	505	$5^9/_{16}$	0.82	0.342
III	69 kv	500, MCM	concentric stranded	285	$6^5/_8$	0.35	0.231
IV	69 kv	1500, MCM	compact segmental	285	$6^5/_8$	0.55	0.330
V	138 kv	1500, MCM	compact segmental	505	$8^5/_8$	1.39	0.302

* Thousand circular mils.

curves, thus avoiding the necessity for a separate determination of this quantity.

From a rigorous standpoint, the effect of dielectric losses may be handled in similar manner by setting up a separate thermal network for these losses and determining a curve of a_d. This has been done for the three systems of Table II having the largest conductor size, and hence the largest dielectric losses, as shown in Fig. 2. In many cases the effect of dielectric loss may be treated with sufficient accuracy by suitably including the dielectric loss with the conductor loss.

The calculation of pressure involves the viscosity of the oil which is dependent upon the oil temperature T_0

$$T_0 = T_0' \pm Qh_0 \text{ C} \qquad (3)$$

where T_0' is the initial oil temperature and h_0 is the unit temperature-time transient of the oil in thermal ohm feet. The sign of the second term depends upon whether load is added or dropped. Curves of h_0 for the cable systems of Table II are shown in Fig. 1. When the dielectric loss is not included with the conductor loss, equation 3 may be extended by the term ΔT_{0d} representing the temperature change in the oil from dielectric loss. Curves of ΔT_{0d} are given in Fig. 2.

In cases where a given load is dropped before the steady-state conditions resulting from that load have been attained, the corresponding oil demand that a' may be found as follows. If the load is dropped at time t_0 after its application, at a subsequent time $t' = t_0 + \Delta t$

$$a' = a_t' - a_{\Delta t} \text{ inches}^3 \text{ per foot-second} \qquad (4)$$

in which a_t' represents the value of the a curve at time t' and $a_{\Delta t}$ its value at time Δt. In calculating the maximum value of a' occurring after dropping load, it is sufficient to assume that Δt is equal to the time at which the a curve is a maximum. It will be noted that if the load has continued long enough for steady-state conditions to prevail, equation 4 becomes equal to equation 2 with change of sign.

Corresponding values of h_0' and $\Delta T_{0d}'$ for use in equation 3 are determined in similar manner.

Calculation of Oil Flow

If L is the length of the line in feet, it will be apparent that the amount of oil which will flow into or out of the line as a function of time after dropping or increasing load is

$$0_l = 4.33 L \Delta V \times 10^{-6} \text{ gallon} \qquad (5)$$

The seasonal line oil change is obtained by substituting the seasonal change in ambient temperature ΔT_a for ΔT_c, ΔT_t, ΔT_0, and ΔT_p in equation 1.

$$0_s = 3L\Delta T_a[D_0^2 - (D_c^2 + 1.3D_s^2)] \times 10^{-6} \text{ gallons approximately} \qquad (6)$$

Required Pump Capacity

The rate of oil flow after dropping or increasing load is

$$F = 0.26La \text{ gallons per minute} \qquad (7)$$

The required pump capacity is the maximum value of equation 7.

Calculation of Pressure

When oil is required by the line, the pumping pressure which must be developed is that required to maintain the desired minimum pressure at the "worst" point of the line aided or opposed by the hydrostatic pressure resulting from change in elevation along the line P_h and to overcome the friction developed in supplying the additional oil P_f. If Δh is the change in elevation at any point of the line and γ is the specific gravity of the oil, at that point

$$P_h = 0.434\gamma\Delta h, \text{ psi} \qquad (8)$$

The frictional pressure P_f varies as the square of the distance from the closed end, and is composed of two parts, that developed in the main pipe and that developed in the by-pass system. As indicated in Appendix I, P_f may be expressed by the relationship

$$P_f = P_m + P_b = 35.5x^2 a\mu \left(\frac{K}{D_0^4} + \frac{N}{L}\frac{l}{D_b^4}\right) \times 10^{-6} \text{ psi} \qquad (9)$$

in which μ is the viscosity of the oil in centipoises, x is the distance from the closed end in feet, L is the length of the main pipe in feet, l is the effective length of a by-pass system in feet and N is the number of by-pass systems. The factor K depends upon the relative size of the cables and their position in the pipe.

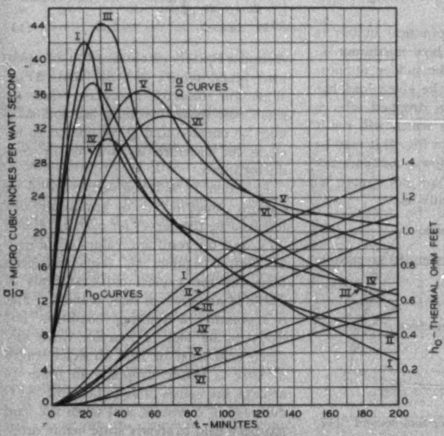

Fig. 1. Curves of a/Q and h₀ as functions of time for the pipe-type cable systems of Table II

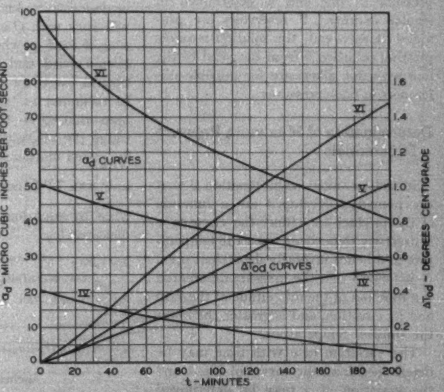

Fig. 2. Curves a_d and ΔT_{0d} as functions of time for the larger pipe-type cable systems of Table II

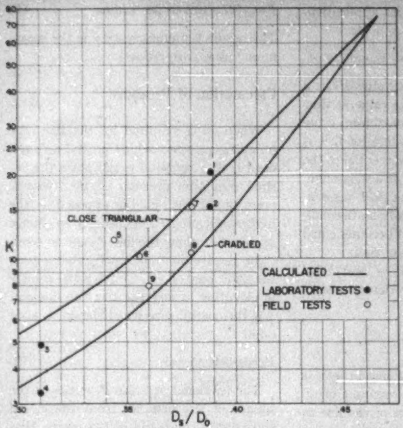

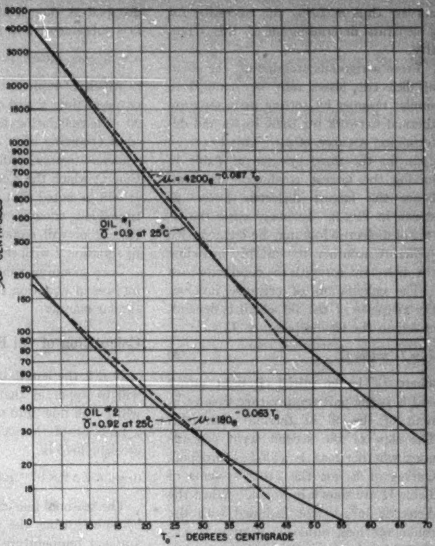

Fig. 3 (above). Calculated and measured values of the factor K as functions of the cable to pipe diameter ratio

Fig. 4 (right). Oil viscosity as a function of temperature

Curves of K as a function of the ratio D_s/D_0 are given in Fig. 3 for close triangular and cradled spacings. The development of these curves is discussed in Appendix I.

The maximum pumping pressure required is determined by plotting equations 8 and 9 over the length of line in order to determine the worst point. The calculation of the maximum internal pressures built up within the system upon the application of load and with the system discharging into a reservoir at a given back pressure at one end is determined in similar manner. If reservoirs are provided at each end, the solution requires plotting equation 9 from each end of the line with due allowance for possible differences in back pressures.

Determination of Maximum Pressure Differentials

It will be noted from equation 9 that the pressures developed are a function of the product $a\mu$. Since the viscosity μ is inversely dependent upon the temperature and hence inversely dependent upon Q, it follows that the pressure differential is a function of the magnitude of the load and its duration, and is greater the lower the ambient temperature.

The variation in a with time may be determined from the curves of Fig. 1 and the variation of μ may be determined from equation 3 and the characteristic viscosity-temperature curve of the oil, shown in Fig. 4. Oil no. 1 is typical of the oil used at present in pipe-type cable systems. Oil no. 2 is the type used in low-pressure oil-filled cables and has been included to permit consideration of an oil of lower viscosity where pressure variations would otherwise be excessive. By plotting the product $a\mu$ its maximum value may be determined for any condition of loading.

Nevertheless, as a practical matter it is desirable to know how maximum $a\mu$ will vary with Q on the sudden application of load or when the given load has been carried and then dropped after a critical length of time which will result in maximum $a\mu$. From Fig. 4, it may be seen that over the lower temperature range the viscosity of oil no. 1 may be expressed mathematically as

$$\mu = 4{,}200\epsilon^{-0.087\,T_0} \text{ centipoises} \qquad (10)$$

Thus by equation 3 extended to include dielectric loss

$$\begin{aligned}\mu &= 4{,}200\epsilon^{-0.087\,(T_0' \pm Qh_0 \pm \Delta T_{0d})}\\ &= \mu\epsilon^{-0.087\,(Qh_0+\Delta T_0 d)} \text{ centipoises}\end{aligned} \qquad (11)$$

and

$$a\frac{\mu}{\mu_0} = [Q(a/Q)+a_d]e^{-0.087\,(Qh_0+\Delta T_{0d})}$$
$$\text{inches}^3 \text{ per foot-second} \qquad (12)$$

where μ_0 represents the initial viscosity of the oil.

Since a/Q, a_d, h_0 and ΔT_{0d} are functions of time, by differentiating equation 12 with respect to time and equating to zero, we find that the maximum values of $a\mu$ will occur at the time when

$$Q\frac{d(a/Q)}{dt}+\frac{da_d}{dt} = 0.087\,[Q(a/Q)+a_d] \times \left[Q\frac{dh_0}{dt}+\frac{d\Delta T_{0d}}{dt}\right] \text{ inches}^3 \text{ per foot-second}^2 \qquad (13)$$

A similar equation is obtained on dropping load based on a', a_d', h_0', and $\Delta T_{0d}'$. When the dielectric losses are relatively small, the terms involving a_d and ΔT_{0d} may be omitted and Q considered to include the dielectric as well as the conductor losses.

Equation 13 may be solved for Q at various values of time by graphically differentiating the curves for a/Q, a_d, h_0 and ΔT_{0d} and the resultant values of $a\mu$ may be plotted against Q. This has been done for the typical cable systems of Table II as shown in Figs. 5 and 6. Fig. 6 represents a limiting condition not likely to be met in practice since any given load must be held an exact length of time t_0 before dropping in order to achieve the values of μa indicated. As Q decreases t_0 increases, and when the load has been held to steady state before dropping ($t_0 = \infty$) the corresponding value of Q is determined by differentiating equation

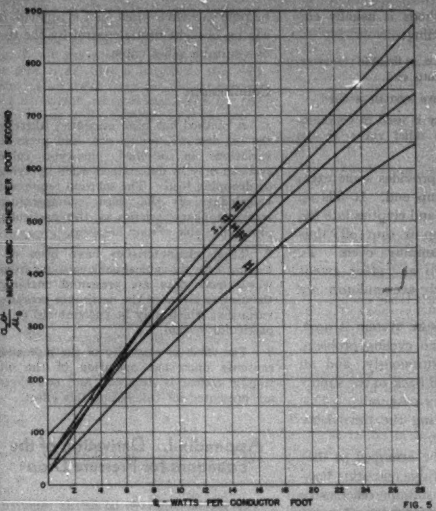

Fig. 5. Maximum value of $a\,\mu/\mu_0$ as a function of suddenly applied load

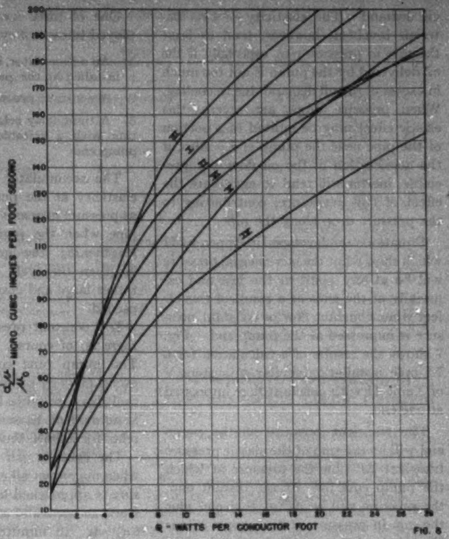

Fig. 6. Maximum value of $a'\mu/\mu_0$ as a function of load dropped

12 with respect to Q and then equating to zero.

Thus, neglecting dielectric loss

$$Q=\frac{11.5}{h_0'}=\frac{11.5}{H_{0e}-(h_0)_{\Delta t}}\text{ watts per foot}\qquad(14)$$

and

$$a\frac{\mu}{\mu_0}=4.2\frac{a'/Q}{h_0'}=\frac{4.2(a/Q)\text{ max}}{H_{0e}-(h_0)_{\Delta t}}$$

inches³ per foot-second (15)

where h_0' and a'/Q are ultimate values ($t_0=\infty$), and $\Delta t=t$ for maximum a/Q.

Effect of the Elastic Transient

When the cable system is operated at constant pressure, or over a very narrow pressure range, the pressure changes produced by a slow thermal transient will be affected little, if at all, by the elastic properties of the system. However, in a pipe cable fed by a constant-flow oil pump of considerable capacity the usual practice is to permit the pressure to drop materially below the normal operating level during cooling, then to restore it to a point somewhat above the normal operating level by means of a rapid-pumping operation.

If the flow resistance is low, the pipe will come up to pressure fairly uniformly. But if low temperatures, high oil viscosity and restricted flow areas, either in the pipe itself or in the feed line from the pump, or the by-pass system combine to produce high-flow resistance, the elastic properties of the system, and particularly the compressibility of the oil and the extensibility of the pipe, may become important.

If the pipe and its contents were absolutely rigid, a very slight oil contraction during cooling would drop the pressure to zero. Then the pump would start, and would replace the oil lost by contraction, after which the pressure would tend towards infinity unless the feed were reduced to a value equal to or less than the

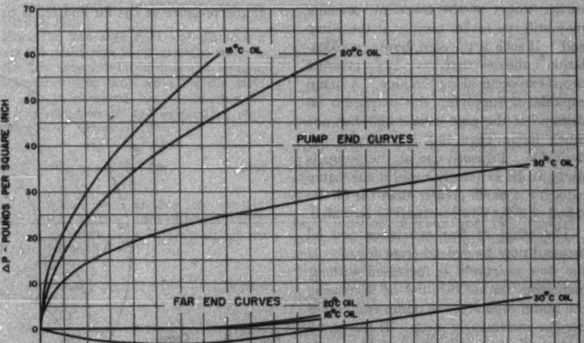

Fig. 7. Typical pipe-type cable elastic pressure transients for a 7.5-mile installation similar to system V of Table II with constant flow impressed at one end

oil demand. The elasticity of the materials involved, however, tend to limit the rate of pressure rise, especially if the oil delivered by the pump is not too much in excess of the oil demand due to cooling. When pressure drops are severe, this elastic effect may be limited to a portion of the pipe near the pump end. Also, if the acceleration of the oil flow is appreciable, inertia will tend to aggravate the effect of flow resistance, contributing to the pressure drop along the pipe.

Equations are developed in Appendix II which show what the incremental pressure will be at any point in the line and especially at the ends as a result of this effect when constant flow or constant pressure is impressed at the pump end. Fig. 7 shows the results of a calculation for a 7.5-mile installation similar to system V of Table II with constant flow impressed at one end.

The transient pressure at the pump end will be the sum of the elastic pressure transient ΔP plus the pressure at which the pump cuts in. At the distant end, the pressure will be ΔP at that end plus the cut in pressure of the pump minus P_h.

The elasticity of the system tends to maintain pressure at the far end of the line over what would exist if the pressure drop due to the flow necessary to supply the oil demand were the only factor present.

At the pump end, the pressure rises rather rapidly because the pump is feeding in more oil than the pipe can absorb because of the oil demand. Even though the pump capacity may be lower than the oil demand of the entire pipe during the earlier stages of the transient, pressure may still rise rather rapidly at the pump end. If such is the case, however, calculation indicates that very large pressure drops can occur along the pipe. A pump capable of supplying the maximum oil demand of the pipe is advisable but one much larger than this is generally not desirable. Pressure rise at the pump is likely to be extremely rapid if the pump capacity is much greater than the oil demand or if the flow resistance is very high.

The effect of flow resistance and oil demand may be judged from Fig. 7. If the flow resistance is increased without increasing the oil demand or decreasing the pump capacity, the pump end curves become increasingly steep. If the pump is shut off after an increase of 40 pounds per square inch, for instance, under the conditions shown in Fig. 7, it will run for about 1 minute with oil at 15°C, and therefore some cycling of the pumping equipment will occur.

One of three methods is usually employed to control cycling:

1. An accumulator, i.e., a flexible reservoir, is installed at the pump end.
2. A constant pressure system is used.
3. A time delay relay is used in combination with a suitable relief valve at the pump end.

The accumulator provides some extra elasticity at the pump end. It fills up as pressure increases and empties into the pipe when the pump is shut off, thus lengthening the pumping cycle. To lengthen the cycle to any great extent rather large and costly accumulators are needed.

If a constant pressure system is used, there is, of course, no cycling problem. The pump runs continuously, and all excess oil is by-passed back to the supply tank by a suitable by-pass valve. This is equivalent to setting the time delay relay for infinite time.

The controls can be arranged so that when maximum allowable operating pressure is approached a suitable relief valve starts to open, and a time delay relay, set for, say, 10 minutes' delay is started. This arrangement permits the pump to maintain a substantially constant pressure on the pipe for a limited time by bypassing back to the supply tank the excess oil which the pipe cannot absorb without pressure increase. After this time the time delay relay shuts down the pump, which procedure is found to reduce cycling frequency very greatly. It is, of course possible to control cycling frequency between almost any reasonable limits that may be desired by adjusting the time delay relay.

If the pressure at the far end tends to become excessive when load is applied, it can be brought under control by the use of a suitable relief valve.

Conclusions

1. A method has been presented whereby the oil demand, pump size, and pressure variations in oil-filled pipe-type cable systems may be determined when applying or dropping load. The solution requires a knowledge of the basic temperature transient characteristics of the particular pipe-type cable system involved.
2. These characteristics have been determined for six typical cable systems from which basic data are presented enabling the user to estimate the maximum pressure variations which may be encountered on a particular system.
3. The effect of elasticity of the pipe and contents upon the operation of the oil supply system is discussed and equations are presented for calculating this effect.

Appendix I. Derivation of the Equations for Pressure Drop

The pressure differential dP/dx required to maintain a laminar oil flow of F cubic inches per second in the main pipe having an inside diameter D_0 inches may be expressed by a modification of Poiseuille's law

$$\frac{dP}{dx}=71\frac{\mu F}{D_0^4}K\times10^{-6}\text{ psi per foot} \qquad (16)$$

where μ is the viscosity of the oil in centipoises. The factor K has been added to care for the obstructions caused by the three cables, and represents the ratio of pressure differential in the pipe with cables to the pressure differential for the same flow without cables. The value of K for a particular cable and pipe configuration may be determined approximately by the following method.

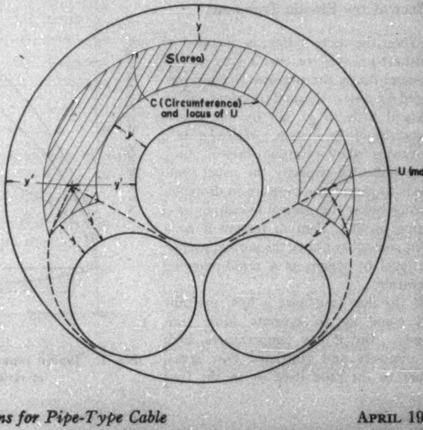

Fig. 8. Cross section of a pipe-type cable system showing factors affecting the determination of the pressure drop

Consider an oil stream of cross-sectional area s square inches and of c inches' circumference, as shown in cross-section in Fig. 8. If the pressure differential along the pipe is dP over a length dx this will result in an axial force on the oil stream of $s\ dP$ which must be balanced by the shear at the wall $cdxf$, where f is the shear force per unit area. Thus

$$\frac{dP}{dx}=12\frac{c}{s}f \text{ psi per foot} \qquad (17)$$

For laminar flow assuming that the flow velocity is the same at equidistant points from any boundary

$$f=0.145\mu\frac{du}{dy}\times 10^{-6} \text{ psi} \qquad (18)$$

where u is the flow velocity in inches per second at y inches distance from the boundary. When equation 18 is substituted in equation 17

$$\frac{dP}{dx}=1.74\mu k\times 10^{-6} \text{ psi per foot} \qquad (19)$$

where

$$k=\frac{c}{s}\frac{du}{dy} \text{ per inch-second} \qquad (20)$$

Thus

$$u=k\int_0^y \frac{s}{c}\,dy=k\int_0^y \frac{1}{c}\left(\int_y^{y'} c\,dy\right)dy \text{ inches per second} \qquad (21)$$

where s and c are functions of y. The total flow F is equal to the integral of the product of u by the differential flow area $c\,dy$

$$F=\int_0^{y'} ucdy = k\int_0^{y'} c\left[\int_0^y \frac{1}{c}\left(\int_y^{y'} c\,dy\right)dy\right]dy \text{ inches}^3 \text{ per second} \qquad (22)$$

If there are no cables in the pipe, the operations indicated by equation 22 may be solved mathematically. Thus

$$F=k\int_{D/2}^{0} -2\pi r\left[\int_{D/2}^{r} -\frac{1}{2\pi r}\left(\int_r^{0} -2\pi r dr\right)dr\right]dr = \pi\frac{D_0^4 k}{128} \text{ inches}^3 \text{ per second} \qquad (23)$$

In this case, since the lines of equal velocity are actually at uniform distances from the boundary, the substitution of equation 23 in equation 19 gives Poiseuille's law (equation 16 with $K=1$). With cables in the pipe, the assumption that the lines of equal velocity are at uniform distances from the boundary surfaces is not strictly correct. In the absence of a more rigorous treatment, however, the procedure indicated will serve as a guide, and it agrees reasonably well with experimental data.

The integrations indicated by equation 22 may be carried out graphically with the aid of a cross-section diagram drawn to scale for the particular cable configuration assumed and similar to Fig. 8. The corresponding value of K for use in equation 16 is obtained by comparing the results of this process with equation 24. Values of K thus determined for several D_s/D_0 ratios with the cables in close triangular and in cradled conformation are illustrated in Fig. 3.

The back calculation of K from field tests may be subject to considerable error because of the difficulty of measuring the oil temperature and hence determining the effective viscosity throughout the test length, and because of uncertainty as to the actual cable configurations. To obtain a check under controlled laboratory conditions, three 40-foot lengths of either standard 1$^1/_2$-inch or 2 inch pipes provided with 1/16×3/16-inch D-shaped skid wires were placed inside of an 80-foot length of standard 6-inch steel pipe in either close triangular or cradled conformation. A differential manometer was connected to a 30-foot gauge section of the 6-inch pipe and oil of 600 to 2,100 centipoises viscosity was passed through the pipe at flow rates of from 1/2 to 7$^1/_2$ gallons per minute. The results of these tests and of available field tests are summarized in Table III and are plotted in Fig. 3.

Table III. Measured Values of K

Test No.	Source	Cable Configuration	Length, Feet	D_s/D_0	μ	K
1	Phelps Dodge Laboratory	close triangular	30	0.388	590	21.7
					1,140	20.2
					1,320	19.4
					1,740	20.4
					weighted average	20.2
2	Phelps Dodge Laboratory	cradled	30	0.388	1,300	15.7
					1,480	15.5
					1,580	15.6
					2,140	15.0
					weighted average	15.3
3	Phelps Dodge Laboratory	close triangular	30	0.310	1,380	4.9
4	Phelps Dodge Laboratory	cradled	30	0.310	1,400	3.3
5	Philadelphia Electric Company	in field	6,937	0.345	69	11.7
6	Consolidated Edison Company	in field	5,810 1,250	0.350 0.380	605	10.2
7	Consolidated Edison Company	in field	13,500	0.380	530	15.4
8	Consolidated Edison Company	in field	13,500	0.380	540	10.5
9	City of Memphis	in field	52,083	0.360	310	8.0

Since the flow rate F at any distance x along the main pipe is equal to xa where a is the flow rate developed in a unit section, the pressure drop built up along the main pipe P_m is obtained by substituting xa for F in equation 16 and integrating with respect to x. Thus

$$P_m=35.5x^2\frac{K}{D_0^4}a\mu\times 10^{-6} \text{ psi} \qquad (24)$$

If the main pipe is divided into sections by N by-pass systems each of length l feet, the total pressure drop P_b built up in the by-pass systems ($K=1$) is

$$P_b=71\frac{l}{D_b^4}[1+2+3\ldots(N)]\frac{L}{N+1}a\mu\times 10^{-6} = 35.5N\frac{l}{D_b^4}La\mu\times 10^{-6} \text{ psi} \qquad (25)$$

Since P_b may be assumed to vary as x^2

$$P_f=P_m+P_b=35.5x^2\left[\frac{K}{D_0^4}+\frac{N}{L}\frac{l}{D_0^4}\right]a\mu\times 10^{-6} \text{ psi} \qquad (9)$$

Appendix II. Derivation of Equations for the Elastic Transient

The pipe and its contents may be considered analogous to a transmission line having series resistance and inductance and shunt capacitance and leakage. The flow F in cubic inches per second is analogous to electrical current and the flow resistance B in pound seconds per square inch per cubic inch per foot corresponds to electrical resistance. The inertia M in pound seconds per square inch per foot is analogous to inductance, and the elastic volume change V_e in cubic inches per foot per psi corresponds to electrical capacitance. Thus from equation 16

$$B=71\frac{\mu K}{D_0^4}\times 10^{-6} \text{ psi seconds per inch}^3 \text{ foot} \qquad (26)$$

$$M=\frac{1430\gamma}{D_0^2-3D_t^2}\times 10^{-6} \text{ psi second}^2 \text{ per inch}^3 \text{ foot} \qquad (27)$$

and

$$V_e=\frac{3\pi}{E_s}(D_0^2-1.5D_t^2)\left(\frac{2D_0}{D_p-D_0}+\frac{E_s}{E_0}\right) = 45(D_0^2-1.5D_t^2)\left(1+0.0145\frac{D_0}{D_p-D_0}\right)\times 10^{-6} \text{ inches}^3 \text{ per psi foot} \qquad (28)$$

when γ is the specific gravity of the oil, E_s is Young's modulus for the steel of the pipe (29×10^6 psi) and E_0 is the bulk modulus of the oil (0.21×10^6 psi).

The oil demand a, however, which is a fixed function of time and the thermal properties of the system, is not exactly analogous to transmission line leakage which is independent of time.

The differential equations to be solved, therefore, are

$$\frac{dP}{dx}=FB+M\frac{\partial F}{\partial t} \text{ psi per foot} \qquad (29)$$

$$\frac{dF}{dx}=a+V_e\frac{\partial P}{\partial t} \text{ inches}^3 \text{ per foot second} \qquad (30)$$

If the pipe is closed at the far end, and the pump starts supplying oil at constant rate F_0, the solution for ΔP, the transient pressure increment is

$$\Delta P=\frac{F_0 t}{LV_e}-\frac{1}{V_e}\int_0^t a\,dt+2F_0BL\times \sum_n \phi(nx)[2\alpha\beta_1+(\alpha^2+\beta_1^2)\epsilon^{-\alpha t} \cos(\beta_1 t-\theta_1)]\text{ psi} \quad (31)$$

where

$$\alpha=\frac{B}{2M}\text{ per second}$$

$$\beta_1=\sqrt{\frac{(n\pi/L)^2}{MV_e}-\alpha^2}\text{ per second}$$

$$\phi(nx)=\frac{(-1)^n}{2\alpha\beta_1(n\pi)^2}\cos\frac{n\pi x}{L}=\phi'(n)\cos\frac{n\pi x}{L}$$

$$\theta_1=\frac{\alpha^2-\beta_1^2}{2\alpha\beta_1} \quad (32)$$

At the pump end, this becomes

$$\Delta P=F_0\left(\frac{t}{LV_e}+\frac{BL}{3}\right)-\frac{1}{V_e}\int_0^t a\,dt+ 2F_0BL\sum_n(-1)^n\phi'(n)(\alpha^2+\beta_1^2)\epsilon^{-\alpha t}\times \cos(\beta_1 t-\theta_1)\text{ psi} \quad (33)$$

At the far end, this becomes

$$\Delta P=F_0\left(\frac{t}{LV_e}-\frac{BL}{6}\right)-\frac{1}{V_e}\int_0^t a\,dt+2F_0BL\times \sum_n \phi'(n)(\alpha^2+\beta_1^2)\epsilon^{-\alpha t}\cos(\beta_1 t-\theta_1)\text{ psi} \quad (34)$$

The expression

$$\frac{1}{V_e}\int_0^t a\,dt\text{ psi}$$

may be evaluated by graphically or numerically integrating the appropriate a/Q curve of Fig. 1 out to the given value of t and multiplying by Q/V_e.

If a constant pressure P_0 is impressed by the pump, the solution for ΔP is

$$\Delta P=P_0\times \left[1+2\sum_n \psi(nx)\epsilon^{-\alpha t}\cos(\beta_2 t-\theta_2)\right]+ \frac{2}{V_e}\sum_n \psi(nx)\int_0^t a(\tau)\epsilon^{-\alpha(t-\tau)}\times \cos[\beta_2(t-\tau)-\theta_2]d\tau\text{ psi} \quad (35)$$

where

$$\beta_2=\sqrt{\frac{(2n-1)(\pi/2L)^2}{MV_e}-\alpha^2}\text{ per second}$$

$$\theta_2=\tan^{-1}\frac{\alpha}{\beta_2}$$

$$\psi(nx)=\frac{(-1)^n}{\beta_2\sqrt{MV_eL^2}}\cos\frac{(2n-1)\pi}{2}\frac{x}{L} =\psi'(n)\cos\frac{(2n-1)\pi}{2}\frac{x}{L} \quad (36)$$

The expression $a(\tau)$ is the value of a at $t=\tau$. At the far end, this becomes

$$\Delta P=P_0\times \left[1+2\sum_n \psi'(n)\epsilon^{-\alpha t}\cos(\beta_2 t-\theta_2)\right]+ \frac{2}{V_e}\sum_n \psi'(n)\int_0^t a(\tau)\epsilon^{-\alpha(t-\tau)}\times \cos[\beta_2(t-\tau)-\theta_2]d\tau\text{ psi} \quad (37)$$

The expression

$$\frac{2}{V_e}\sum_n \psi'(n)\int_0^t a(\tau)\epsilon^{-\alpha(t-\tau)}\times \cos[\beta_2(t-\tau)-\theta_2]d\tau\text{ psi}$$

may be evaluated for a given value of t as follows:

1. Calculate β_2 and θ_2 for $n=1$. Also calculate α.
2. Calculate several values of $t-\tau$ over a range of time $\tau=0$ to $\tau=t$.
3. For each value of τ, evaluate $\epsilon^{-\alpha(t-\tau)}\cos[\beta_2(t-\tau)-\theta_2]$, and multiply by $Q[a(\tau)/Q]$, obtaining $a(\tau)/Q]$, from the appropriate a/Q curve of Fig. 1 taken at time $t=\tau$.
4. Evaluate this integral, using either a planimeter, or numerical method between time 0 and time t.
5. Now, multiply by $\psi'(n)$ for $n=1$.
6. Repeat calculations 1 to 5 for $n=2$ and $n=3$.
7. Add the results, and multiply the sum by $2/V_e$.

Fig. 7 shows the application of equations 32, 33, and 34 to a long pipe cable. In preparing these curves an allowance was made for a 2-second period during which the pump was coming up to speed. During this time the flow was assumed to be proportional to time.

Appendix III. Calculation of the Oil Demand and Pressures for a 69-Kv 1,500,000-Circular-Mil Oil-Filled Pipe-Type Cable System (System IV of Table II)

For basic parameters see Table IV.

Calculations of Oil Flows

Seasonal from 5 to 25 C ambient by equation 6

$$0_s=3\times 35{,}000\times 20\times 30.2\times 10^{-5} =635\text{ gallons}$$

For full load of 880 amperes continuously, by equation 1

$$\Delta V=0.0072\Delta T_c+0.0232\Delta T_i+0.1770\Delta T_o- 0.0132\Delta T_p$$

$$\Delta T_c=7.9\times 6.70=53$$

$$\Delta T_i=7.9\times 6.18=49$$

$$\Delta T_i=7.9\times 5.20=41$$

$$\Delta T_p=7.9\times 4.67=37$$

Therefore, $\Delta V=8.28$, and by equation 5, the oil expelled by sustained full load is

$$0_l=4.33\times 35{,}000\times 8.28\times 10^{-3} =1{,}250\text{ gallons}$$

Hence, the reservoir capacity should be at least

$$635+1{,}250=1{,}885\text{ gallons}$$

Required Pump Capacity

The maximum rate at which the pump may be required to supply oil will obtain if full load continuously held is increased to 1,040 amperes for 4 hours and then dropped. From Fig. 1 for system IV and equation 4 for the base load

$$a'/Q=(0-30.8)\times 10^{-6}=30.8\times 10^{-6} \text{ inches}^3\text{ per foot second}$$

and extrapolating for the additional transient load

$$a'/Q=(10.8-30.8)\times 10^{-6}=20\times 10^{-6} \text{ inches}^3\text{ per foot second}$$

Thus by equation 7

$$F=0.26\times 35{,}000[7.9\times 30.8\times 10^{-6}+ (10.2-7.9)\times 20\times 10^{-6}] =2.63\text{ gallons per minute}$$

Calculation of Pressures

Assuming close triangular configuration, from Fig. 3 $K=8$.

By equations 8 and 9

$$P_h=0.434\times 0.9\times 114=47\text{ psi}$$

$$P_f=35.5\times(35)^2\left[\frac{8}{(6.13)^4}+\frac{19}{35{,}000}\times \frac{12.36}{(2.07)^4}\right]a\mu=264a\mu\text{ psi}$$

Table IV. Basic Parameters

Diameters, Inches	Steady-State Thermal Resistances	Miscellaneous
$D_c=1.41$	$H_{cs}=6.70$	$L=35{,}000$ feet
$D_i=1.98$		$N=19$ by-pass sections
$D_s=2.02$	$H_{is}=6.18$	$l=12.36$ feet per section
$D_o=6.13$	$H_{os}=5.20$	$\Delta h=114$ feet at end of line
$D_p=6.63$	$H_{ps}=4.67$	$\gamma=0.9$ (Oil no. 1)
$D_b=2.07$		$Q_d=0.55$ watts per foot
$D_s/D_o=0.33$		$R_{dc}=8.60$ microhms per foot at 75 C R_{ac}/R_{dc} at conductor $=1.105$

Full load = 880 amperes; Q (including Q_d) $=(880)^2\times 8.60\times 1.105\times 10^{-6}+0.55=7.35+0.55=7.9$ watts per foot.

Emergency = 1,500 amperes for 15 minutes, $Q=21.6$ watts per foot, followed by 1,040 amperes for 225 minutes, $Q=10.2$ watts per foot.

If full load of 880 amperes is suddenly applied with an ambient of 5 C, the maximum value of P_f from Fig. 5, system 4 for $Q=7.9$, and from Fig. 4 for 5 C is

$$P_f=264\times225\times10^{-6}\times2,700=160 \text{ psi}$$

Thus the maximum internal pressure for a normal pressure of 200 psi at the elevated end is

$$200+160=360 \text{ psi}$$

If an emergency load of 1,040 amperes with an ambient of 5 C is dropped after the critical time which will yield the maximum value of P_f from Fig. 6 for $Q=10.2$

$$P_f=264\times94\times10^{-6}\times2,700=67 \text{ psi}$$

Assuming that a minimum pressure of 75 psi is required to suppress ionization, the minimum pumping pressure required is

$$75+47+67=189 \text{ psi}$$

which will occur 33 minutes after the load is dropped (see curve IV of Fig. 1) provided that the load was carried for the critical length of time.

The critical value of a sustained load for maximum P_f after dropping may be obtained by equation 14

$$Q=\frac{11.5}{5.20-0.17}=2.29 \text{ watts per foot}$$

The corresponding load current is

$$I=\sqrt{\frac{2.29-0.55}{1.105\times8.60\times10^{-6}}}=428 \text{ amperes or}$$

48.5 per cent full load

By equation 14 with a 5 C ambient

$$a\mu=4.2\times2,700\times\frac{30.8\times10^{-6}}{5.20-0.17}=0.070$$

Therefore, starting from steady-state conditions the maximum pressure loss which will occur on dropping load is

$$P_f=264\times0.070=18 \text{ psi}$$

Discussion

E. H. Kirkham (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): This paper offers a new and very useful tool for pipe cable design, and the committee is to be complimented on a fine piece of work.

Since the advent of pipe cable, pipe size has been based on the allowable clearance between the cable and the pipe, clearance being defined as the distance between the inside top of the pipe and the top of the three cables in triangular arrangement.

There has been no unanimity of opinion as to what that minimum clearance should be. Recommendations ranged from 1 to 0.25 inch, and economic considerations governed exclusively. We recently had a case of a 5-mile line where a 7/8-inch clearance would admit the use of a 4-inch inside diameter pipe, but application of the equations in the paper disclosed that the use of such 4-inch pipe would result in pressures over 700 psi on increasing load. When 5-inch pipe was considered, we found that this pressure was under 300 psi.

These values would obviously have been lower with a shorter line, which leads to the generalization that for short lines the clearance should control, while for lines over about 3 miles the hydraulic characteristics might well determine the pipe size.

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.): When considering the use of a larger pipe to reduce flow resistance, it might be feared that this would increase "oil demand" because of the larger volume of oil. It would appear, however, that the increased volume would be almost exactly offset by the lower rate of temperature rise within the pipe caused by the greater thermal storage capacity. Thus 10-watt power absorbed in heating 1 gallon of oil will produce exactly the same rate of expansion (milliliters per hour) as if absorbed in 2 gallons. Thus the advantage of the reduction in flow resistance by the larger pipe will be fully realized without a partial offset by increase of oil demand. Of course, the larger pipe will cause an extension in the time during which oil will flow and will require increased reservoir capacity. Even this small disadvantage is accompanied by a significant advantage in that the greater thermal storage capacity given by the large pipe will improve the peak load "ampacity."

John C. Parker (Memphis Light, Gas and Water Division, Memphis, Tenn.): It is the intent of this discussion to present the results of field tests, on one pipe-type cable circuit, which unfortunately could not be completed until after the preparation of the paper. The characteristics of this circuit are as follows:

Voltage, 115 kv
Conductor, round, compact strand, 500,000 circular mils
Insulation, 435 mils
Pipe, outside diameter, $5\,{}^{9}/_{16}$ inches
Q_d, watts per foot, 0.48
D_s/D_0, 0.339

The oil viscosity-temperature curve is the same as oil no. 1 in Fig. 4.

The average measured value of K for a 14,140-foot circuit of this cable was 4.5 for an oil viscosity of 530 centipoises and flow rates of 4.03 to 6.16 cubic inches per second.

Measured values of oil demands, a/Q and the unit temperature, time, transient of the oil, h_0 are given in Fig. 9. It should be noted that the front of the a/Q curve is dependent on the settling of the oil pressure relief devices.

The maximum measured value of a_μ/μ_0 was 234 microcubic inches per foot per

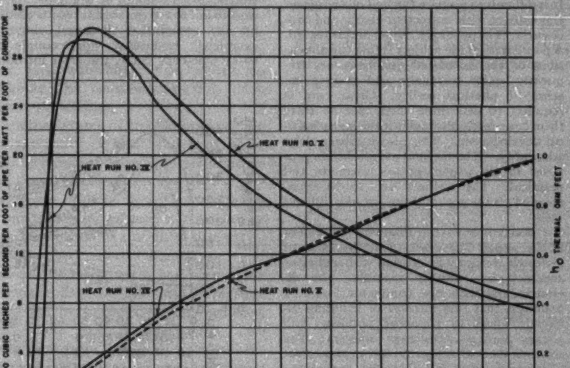

Fig. 9. Measured values of oil demands, a/Q unit, temperature time transient of the oil h_0, 115-kv high-pressure oil-filled cable

second for 8.0 watts per conductor foot when load was suddenly applied to the cable circuit, and 42 microcubic inches per foot per second for 3.5 watts per conductor foot when the load was dropped. It was surprising to find such excellent agreement of the theoretical values given in the paper and actual measurements in the field.

E. H. Grosser and **R. L. Rowan** (Commonwealth Edison Company, Chicago, Ill.): While the determination of transient oil pressures and oil flow in low-pressure oil-filled cable has been the subject of a number of papers presented before the AIEE, there have been no corresponding presentations of methods dealing with transients in high-pressure oil-filled pipe-type cables. This paper gives, we believe for the first time, methods whereby conditions in pipe-type cables may be calculated. It is true that there is a much greater pressure margin in this kind of cable as compared with the low-pressure oil-filled type, because of its higher operating pressures, so that transients that occur in dropping load, for example, cannot result in complete loss of pressure for any normal type of installation. Nevertheless, there are situations in which it becomes desirable to be able to determine pressure and flow conditions for pipe-type cable, and for these situations the Committee report should prove most valuable.

To get the temperature transient for pipe cable, it is necessary to refer to a paper by Mr. Neher (ref. 6 of the paper). It would be helpful, we think, if a set of sample calculations covering this part of the determination could be made available for the specific cable shown in the pressure transient calculations of the present report. It is suggested that this addition could be covered in the closing discussion.

F. O. Wollaston (British Columbia Electric Company, Ltd., Vancouver, B. C., Canada): It is difficult to prepare the text of a paper on this subject with consistent clarity and conciseness. The paper is a model in this regard. A peculiarity of the subject is that the dimensions of the calculated quantities are frequently quite unwieldy and convey no sense of physical reality. Great care is required to determine them and to state them completely throughout the mathematical development. This also has been done admirably. The method of calculation proposed in the paper appears adequate and practical. The authors are to be commended on the accomplishment of a difficult task.

I disagree with the following statement in the paper: "In many cases the effect of dielectric loss may be treated with sufficient accuracy by suitably including the dielectric loss with the conductor loss." I maintain that this method of handling dielectric losses in transient problems will always lead to erroneous answers. The rigorous method suggested in the paper, but not developed in detail, is the proper approach. A method of handling dielectric loss transients in Pirelli-type oil-filled cable with acceptable accuracy is given in references 3 and 4 of the paper. The basis of my criticism of the quoted statement follows. The rate of change of temperature at the first instant of a transient is a maximum in the element of the cable wherein the losses have been changed, and is zero everywhere else. For example, if the dielectric losses undergo a change, the insulation will experience at the very first instant the maximum rate of temperature change to which it is to be subjected. On the other hand, the rate of change of temperature in the conductor will be zero at the first instant. If the dielectric loss is considered to occur in the conductor instead of in the insulation, the conductor at the first moment of a dielectric loss transient will be constrained by the mathematics to undergo its maximum rate of temperature change, whereas the insulation will have zero rate of temperature change. This result is the exact opposite of reality. Nothing during the progress of the transient brings the calculated results any closer to reality. These considerations are most important in hydraulic problems, since the oil demand is directly proportional to the rate of temperature change.

Referring to the a/Q curves in Fig. 1, it will be seen that a/Q has a finite value at zero time. This value at zero time results solely from the oil demand contributed by the conductor. At this stage of the transient the cable insulation and the oil in the pipe contribute nothing to the oil demand. During the subsequent stages of the transient, the insulation and pipe oil contribute substantially to the oil demand. Because of their comparatively large volume, their contribution soon overshadows that of the conductor and the peak of the demand curve results. If the dielectric losses were assumed to occur in the conductor, the calculated oil demand transient due to dielectric loss would have exactly the same shape and per-unit value as the a/Q curves. Now turning to the a_d curves in Fig. 2, which were determined by a rigorous method, it is obvious that there is no correspondence whatever between the two sets of curves. This illustrates that the suggested approximate method will not produce results of reasonable accuracy. In many practical problems the effect of dielectric losses is minor or negligible and it is easy to fail to recognize that results obtained by the assumption discussed above are completely erroneous. For example in a 69-kv pipe-type cable, the error introduced by incorrect handling of dielectric losses would probably be negligible. In the first place, the dielectric losses are intrinsically small compared to load current losses. In the second place, the dielectric loss transient affects mainly the cable insulation, which contains only a small part of the total oil in the system. On the contrary, a substantial error might occur in problems involving 230-kv and higher voltage Pirelli-type oil-filled cable. In this case the dielectric losses would be much larger and would affect the majority of the oil in the system, that is, the oil in the insulation.

J. H. Neher: The Working Group is very appreciative of the interest with which this report has been received. As Mr. Kirkham has pointed out, it should furnish a ready means of determining whether or not a pipe size which is satisfactory from a cable-pulling standpoint will permit operation within permissible pressure limits.

Mr. Atkinson's observation that the maximum oil demand is substantially independent of the volume of oil employed had not occurred to us, although it is quite evident from Fig. 1, where it will be seen that the maximum values of unit oil demands for systems II and V are roughly the same, despite the fact that the oil volumes are in the ratio of 1 to 3. This is largely responsible for the reasonably close grouping of the curves of Figs. 5 and 6, and enables the user to compute quickly the maximum pressures which may be developed without a detailed transient temperature determination for the particular cable system under consideration.

In this connection, it will be observed that the test data submitted by Mr. Parker represents a maximum oil demand of 30 microcubic inches per second for a loss of 1 watt per conductor. The cable tested by Mr. Parker is somewhat different than any of those studied in the report and the calculated value of maximum unit oil demand is 34 microcubic inches per second. The corresponding value of a μ/μ_0 calculated approximately is equal to 270 microcubic inches per foot per second for a suddenly

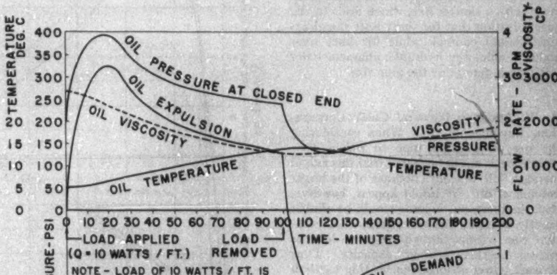

Fig. 10. **Flow conditions on pipe-type cable system with load applied and load removed, 30,000-foot 69-kv 350,000-circular mil $5^{9}/_{16}$-inch pipe, 300 psi maintained at pumphouse**

applied load of 8 watts per conductor foot as against a measured value of 234. The differences between these calculated and measured values amounting to about 15 per cent are not unreasonable considering the difficulties attendant to measurements in the field and the somewhat approximate nature of the basic calculations of the temperature transients involved.

With regard to the latter, Mr. Grosser and Mr. Rowan have suggested that a set of sample transient calculations be included. Unfortunately, space does not permit this, such calculations if made by the method of reference 6 for the four transients required for a given case would be as long as the report itself. As indicated in the report, however, these four transients were determined by an analogue computer (reference 7) and the calculations required after the computer had been set up merely involved multiplying the meter readings by an appropriate constant to obtain the transient temperature rises per unit of conductor loss at the conductor, mid-insulation, oil, and pipe.

Mr. Wollaston is quite correct in his remarks about the theoretically correct method of handling dielectric losses. This was followed in determining the curves of Fig. 2. In the case of cables of 69 kv and under, however, experience has shown that the results obtained are substantially the same whether the dielectric loss is included with the conductor loss or treated separately in a rigorous manner.

To present an over-all picture of what happens when load is picked up and dropped by a pipe-type cable system, Fig. 10 has been prepared. It will be seen that when the load is picked up, the oil pressure at the closed end builds up from an initial value of 200 psi to a maximum value of nearly 400 psi in about 20 minutes, after which it falls off in accordance with the characteristic oil demand curves. However, since the oil temperature is rising and its viscosity is lowering, the pressure will fall off at a faster rate than the oil demand since it depends upon the product of the oil demand by the viscosity.

If the load is sustained, the rate of oil expulsion will decrease to zero and the pressure will return to the initial value of 200 psi. In this particular case, however, the load was dropped after 100 minutes, resulting in a decrease in oil pressure at the closed end to 130 psi, which is less than the initial value of 200 psi, and a change in the direction of oil flow. The duration for which the load has been held before dropping has a pronounced effect upon the resulting pressure drop, and in this case the load has been held for the critical length of time which will result in minimum pressure at the closed end.

Recommendations for Improving Reliability of Stand-by Engine Generators for Microwave Communications Systems

NELSON B. THARP
MEMBER AIEE

IT IS common practice among the users of microwave communications systems to employ engine generator sets for stand-by operation during periods of interruption of the normal power source. Although this practice materially improves the reliability of systems, the engine generator set itself has sometimes proved to be a source of system outage. There are, of course, many causes for engine generator difficulties; however, the majority are traceable to several basic reasons.

The first source of trouble lies in the attempt to apply a standard engine generator unit in a service having highly specialized and rigorous requirements. This action has sometimes been the result of the user not being aware of the real operating problems involved and sometimes from the unavailability of suitable equipment. Experience has shown that standard units, although quite satisfactory for conventional use, may be quite inadequate for microwave stand-by use. Correctly applied, however, stand-by power units can attain a high degree of reliability.

A second source of trouble arises because many of the microwave system users do not have the experience and maintenance techniques vital to keep the engine generator sets in reliable operating condition. This experience comes with time, but meanwhile engine failures can decimate the continuity records of a microwave system.

Another source of trouble originates in the ambiguity or lack of defined terms and techniques describing performance and its measurement for the engine generator sets. Often, there is not a meeting of minds between the user and the engine generator manufacturer until after an installation had proved inadequate.

Considerable progress has been made in overcoming the problems by system users and by technical groups including both users and manufacturers. Two such groups are Radio-Electronics-Television Manufacturers Association (RETMA) Sub-subcommittees TR-14.3.2 and TR-14.3.3 which have proposed standards to establish consistent terminology, practical methods of measuring performance, installation procedure, and, where possible, acceptable standards of performance on engine generator sets for microwave stand-by service.

In this paper it will be attempted to outline practical requirements for purchase and installation of stand-by engine generator sets of 25-kw capacity, or less, for microwave systems. The recommendations are based on the experience of the author, users, and the proposed standards of RETMA committees on stand-by engine generators and housing for microwave. The material is substantially in agreement with the proposed RETMA standards and, in some instances, material has been quoted directly. While sufficiently rigorous to insure satisfactory operation, the requirements are close enough to standard commercial products to avoid any material increase in cost. The requirements will be presented along with a short discussion concerning the reasons for the recommendation.

Ordering and Performance Specifications

ENGINE

Duty. The engine should be capable of continuous unattended operation under rated load for a period of 30 days provided lubricating oil is supplied every 100

Paper 55-42, recommended by the AIEE Carrier Current Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 22, 1954; made available for printing November 17, 1954.

NELSON B. THARP is with the Westinghouse Electric Corporation, Baltimore, Md.

The author is grateful to George F. Thole for some of the information given in the section entitled "Battery Charger."

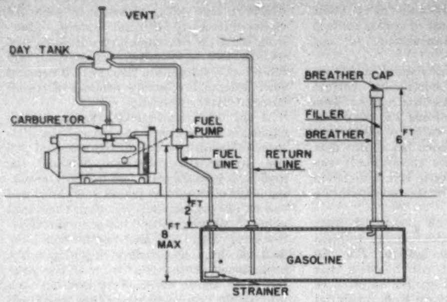

Fig. 1. Recommended installation stand-by engine generator

hours of operation and an adequate fuel supply is available.

This performance can only be expected after the proper break-in procedure, as recommended by the supplier, has been completed.

Speed. The engine shall operate at a nominal speed of 1,800 rpm or less.

Lower speed engines are preferable for durability. 1,200 rpm is desirable, 1,800 rpm is maximum.

Altitude. Standard engines should work at rated load up to 3,300 feet above sea level without any special parts.

Adjustment of carburetors should be all that is necessary for optimum efficiency at altitudes up to 3,300 feet. Equipment for altitudes above 3,300 feet should be so specified to supplier.

Ambient Temperature. The engine shall operate at full rating over the range of +40 to +125 degrees Fahrenheit (F) without auxiliary heaters. With auxiliary heaters, the engine shall operate over the range of −20 to +125 F. At −20 F, the engine shall start and deliver rated power within 30 seconds and, at 0 F, within 15 seconds.

Temperature refers to air ambient to engine including air intake to carburetor. Heaters can be crankcase or cooling-liquid heaters.

Relative Humidity. The engine shall develop rated power at relative humidities up to 85 per cent.

Although engines will generally start and operate at higher humidities, many manufacturers are reluctant to guarantee unconditionally full performance under less than full load conditions. This is because of the occasional icing condition occurring in the carburetion process. However, when the engine is operated near full load, the internal temperature and carburetion allow reliable operation at higher relative humidity percentages. With proper treatment, condensation on ignition components is not a major source of trouble.

Fuels. Gasoline engines shall operate satisfactorily on standard grades of gasoline, natural gas, propane or butane, or mixtures as specified.

Although performance should be satisfactory on standard grades of gasoline, marine or nonleaded gasoline of 80 octane is recommended. This type of gasoline will not foul the carburetor jets with residue during periods of inactivity—a common source of gasoline engine starting failure. Leaded gas accelerates carbon and lead deposits in the combustion chamber and reduces valve life. This is aggravated by the constant speed operation of most stand-by engines. Engine manufacturers recommend that engines in stand-by service be run under load about 30 minutes each week to insure starting when an actual need arises.

Air Intake and Carburetion. Both electric and thermostatic choking shall be provided for gasoline engines. Air intake shall be provided with an oil-bath air filter.

These items are generally standard and deemed necessary for reliable operation and electric and hand-crack starting.

Fuel Pump. Gasoline engines shall include a fuel pump capable of an 8-foot vertical lift. The pump shall be equipped with fuel strainer and sediment bowl and/or strainer. Means for hand-priming shall be provided.

Fuel Day (Gravity) Tank. Gasoline engines will be equipped with a properly vented, 1-quart auxiliary fuel tank to be installed between the fuel pump and the carburetor.

This tank is to insure quick starting by providing, by gravity, replacement fuel for that which evaporates from the carburetor during inactive periods. Return lines should be installed, as shown in Fig. 1.

Fuel Preheaters. Fuel preheaters shall be provided where necessary for efficient starting and operation under temperature conditions specified. An automatic gas control valve shall be provided where fuels other than kerosene or gasoline are used.

Where liquified gas fuels are used in cold climates, special facilities may be required to maintain vaporization rate. The use of liquified butane creates problems at temperatures below +60 F and liquified propane at temperatures below +14 F. A mixtures of these gases will require attention at some temperature between +60 and +14 F.

Ignition. The ignition system shall be adequately protected against failure caused by moisture condensation.

This protection may include covers and silicone treatment of exterior of ignition components. Engine should start even when covered with condensation.

Lubrication System. The lubricating-oil capacity of the engine shall be adequate to permit at least 100 hours of continuous operation on one filling. A pressure and oil-level gauge shall be furnished. Main and connecting-rod bearings shall be pressure-lubricated. A low-oil-pressure cutout switch shall be furnished which will stop the engine before damage when oil pressure falls below a safe operating value.

In general, water-cooled engines will operate over a longer time on one oil filling than air-cooled engines. This is apparently because of a somewhat more uniform cooling with liquid systems which reduces hot spots—a cause of oil deterioration.

Cooling System. Liquid-cooled engines shall be equipped with a pressure type of radiator cap designed to maintain a pressure of not less than 2 pounds per square inch. An adequate pusher-type fan, drawing radiator air away from engine, shall be provided. A thermostat shall be provided to control the operating temperature of the engine to be within the recommended range. A high-water-temperature cutout switch shall be provided to stop the engine if the maximum safe operating temperature is exceeded, as specified for the operating altitude. Maximum operating point of the high-temperature thermostat shall be 210 F. Air-cooled engines shall be equipped with a similar high-temperature cutout switch. The maximum operating temperature of the engine and cooling system shall be such that the temperature of the engine, when stopped, shall not normally rise to the operating point of the cutoff thermostat. If necessary, provisions shall be included to continue to operate the unit at no load for a period of time sufficient to meet this requirement. A suitable guard shall be provided to prevent accidental contact with fan blades, belts, or other moving parts. If an air-exhaust duct is required, suitable fastenings for the duct shall be provided on the engine (radiator frame).

Pressurized radiator caps are to increase the boiling temperatures of the cooling liquid. Pusher-type cooling fans are preferable from a safety and comfort standpoint, since heat and possible exhaust leaks around the engine are drawn away from the engines and through the radiator from where they can be safely ducted to the outside. Thermal overshoot upon stopping an engine must be prevented since restarting is impossible for a period until the engine temperature has returned to the operating range.

Governor Control. Stable engine speed, defined as a speed constant to within 0.8 per cent of final operating speed shall be obtained within 15 seconds after engine has been started. Stable engine speed shall be resumed in no longer than 8 seconds after any sudden change in load including no load to full load. During or after any change of load, the engine speed shall not vary more than 5 per cent. Belt-driven governors are not acceptable.

The limitations on governors, if met, are adequate to allow satisfactory microwave equipment operation even when the generator is supplying a flashing beacon load of 50-per-cent full load. Such a load, of course, may tend to create somewhat more wear on the governor.

Starting System. The starting system shall be sufficient to provide the minimum recommended cranking speed without overheating for 90 seconds. Starter apparatus shall be connected directly to the engine crankshaft or by gears or silent chain drive. Provisions for hand-cranking shall be included. Starting apparatus should be capable of at least five successive starts within a 5-minute period without overheating or damage, if the total operating time does not exceed 90 seconds.

Exhaust System. The exhaust system shall include means of adequate silencing and spark suppression. Exhaust outlets shall be of sufficient size to provide ready installation of commercially available exhaust assemblies. Recommended exhaust assembly and/or maximum allowable back pressure shall be furnished by the engine supplier.

Battery Charger. Equipment shall be provided which will charge starting batteries during the time the engine is running. It may be either a separate engine-driven generator or may be provided by other means. It shall have an adjustable, or automatic, charging rate to allow for the frequency and duration of the engine-operating periods in obtaining correct battery-charge replacement. It shall be capable of replacing starting loss of battery in less than 30 minutes of normal engine operation at 25 degrees Centigrade or more.

If the engine-operating periods are erratic with respect to number and duration, an automatic regulator is the only satisfactory method of getting adequate charge in a normal running period without overcharging on an extended run.

Start-Stop Control. The engine shall be provided with a manual start-stop control clearly marked and easily accessible.

To meet safety rules, this switch must not be placed over 6 feet from the rotating machine.

ALTERNATOR

The alternator shall conform to American Standards Association and National Electric Manufacturers Association motor and generator standards[1] for 50-degree-centigrade rise.

Temperature, Altitude and Relative Humidity. Requirements are the same as for the engine (see section entitled "Engine") except that the alternator shall meet performance requirements at a relative humidity of 95 per cent.

Capacity. The alternator shall be rated in kilovolt-ampere (kva) capacity at 0.8, 0.9 (lagging), and 1.0 power factor. The alternator shall be capable of carrying without damage a 1-minute load of 150 per cent of its rated amperes and a 2-hour load of 125 per cent of its rating.

The requirement for rating the alternator at various typical power factors is necessary because the actual kva capability of synchronous saturated field type of alternators changes with power factor. This is true as the phase of the load current affect the excitation field which in turn materially affects the kva capability. Many such machines rated at 5 kw and 5 kva at power factor=1 will not produce 5 kva at power factor=0.9; see Fig. 2 for example of a typical machine. Purchase orders should specify the voltage, wire arrangement (two or three wire, etc.), kva and power-factor requirements.

Voltage Regulation. Voltage output from no load cold to full load hot shall be within ±5 per cent of rated voltage on unity power-factor loads at an ambient temperature of 70 F. Normal rated voltages are in the range of 110 to 120, single phase, 3 wire, grounded neutral. Under any combinations of load (20 to 100 per cent), power factor (0.8 to 1.0), temperature (−20 F to +125 F), altitude (0 to 3,300 feet), and relative humidity (up to 85 per cent), output voltage shall not vary more than 5 per cent from rated voltage. This shall include conditions where load variations of 20 per cent are occurring at up to a 40-cycle-per-minute rate and where the generator is at either ambient or operating temperature.

The over-all 5-per-cent limitation is necessary as some engine generator guarantees refer to any one, but not any and all combinations of the load, temperature, humidity, altitude, and power factor; yet combinations of extremes often occur in actual practice.

Frequency Regulation. The output frequency shall not vary more than 1 cycle from 60 cycles with a load variation from 20 to 100 per cent.

Where the load uses a voltage regulator sensitive to power frequency, the regulator is usually cut out when the load is shifted to stand-by unit operation.

Wave Shape. Alternators shall meet the applicable American Standards Association standard[2] which requires that the deviation factor of the open-circuit terminal-voltage wave of synchronous

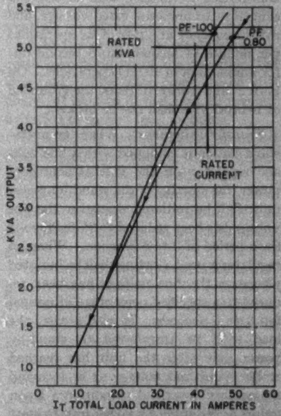

Fig. 2. Gasoline stand-by plant rated 5 kw 5 kva, power factor=100 per cent

machines shall not exceed 0.1. The definition of deviation factor of a wave is the ratio of the maximum difference between corresponding ordinates of the wave and of the equivalent sine wave when the waves are superimposed in such a way as to make this maximum difference as small as possible. An equivalent sine wave is a wave having the same frequency and rms value.

Poor wave shape of power source may in some instances cause malfunctioning of microwave equipment and serious discrepancies in measurement of voltages on some types of instruments.

Starting Control. Alternator shall be equipped with an enclosed control box (National Electrical Manufacturers Association type-1 or equivalent) for relays and contacts to provide electric cranking. Overcranking protection shall be provided which will automatically open the cranking circuit if the engine fails to start after a cranking period of 60 to 90 seconds. The cranking dropout must be reset by hand after a maintenance check to determine the cause of engine malstarting.

AUTOMATIC TRANSFER PANEL

The equipment shall be of suitable design to operate in unattended stations. Temperature, altitude, loads, and power-factor requirements are the same as for the engine (see section entitled "Engine") except that the transfer panel shall meet performance requirements at a relative humidity of 95 per cent.

Rating of Transfer Switch. The line-transfer contactor shall be capable of transferring a resistive load of 125 per cent of rated amperes, rated voltage, and rated frequency at a rate of six operations per minute (4 seconds on, 6 second off) for a minimum of 10,000 operations. On both 2- and 3-wire systems, the grounded or neutral wire shall not be broken.

Transfer Initiations. When the microwave station is equipped with a line-voltage regulator on the normal source of power, the starting of the stand-by power unit shall be initiated whenever the line voltage has been reduced to 95 to 98 volts for a period of 3 to 5 seconds. When no regulator is used, starting shall be initiated whenever the line voltage has been reduced to a specified percentage of normal for 3 to 5 seconds. In either case, the load shall be transferred to stand-by power unit after the unit has reached stable speed and voltage so as to avoid momentary overload condition. Upon failure of the stand-by power unit to start (lack of fuel, etc.), the load circuit shall not be transferred away from normal power source. No chattering of relays is permissible.

The voltage of 95 to 98 volts is chosen as it represents the minimum operating range of line voltage for the average line regulator (115 volts ±17 per cent). When no regulator is used, the minimum satisfactory operating voltage of the microwave equipment must be used to specify the line voltage for transfer initiation. Adjustable time-delay dropout is available from most stand-by suppliers covering a range from 1 to 10 seconds (±1/2 second). Also, adjustable voltage-sensitive dropout relays can be obtained which cover a range of 95 to 110 volts (±1 volt) to accomodate various conditions. Where brief overvoltage conditions are expected, similar facilities should be specified to disconnect the line power and replace it by the stand-by power unit.

Return to Primary Power. When a voltage regulator is used and the normal primary power source is restored to a value 2 to 6 per cent above the dropout voltage for a continuous period of at least 10 minutes, the load shall be transferred back to the primary power source. This transfer should not interrupt the power source by more than 1/4 second. Upon failure of the stand-by power unit while carrying load, the load shall be transferred back to the normal source immediately or at least upon restoration of normal supply. No chattering of relay contacts is permissible.

Adjustable time-delay functions are available from 10 to 30 minutes. In general, it is desirable, once the stand-by engine is started, to leave it running under load for a 20- to 30-minute period. This allows the battery to be recharged and the operating temperature to evaporate accumulated moisture in the lubricating oil. It is not desirable to run the engine any length of time without load as this accelerates the accumulation of carbon with accompanying engine inefficiency and maintenance cost increase. Fuel supply monitoring, local or remote, is desirable to avoid fuel exhaustion where each start means a 20- to 30-minute run under load.

Battery Charger. The transfer panel shall include a starting-battery trickle charger connected to the normal power source having an adjustable charge rate from 0.04 to at least 0.2 amperes. An ammeter and fuse shall be included in this circuit.

Since the condition of the battery will vary with age, the interim charging rate must be adjustable to maintain the optimum battery charge by replacing normal leakage charge. Experience has indicated that many battery failures are the result of excessive charging. Overcharging concentrates the acid which chars the separators, causing a high self-discharge rate resulting in severe sulfation of the plates. This high rate also disintegrates the positive grids, allowing the active material to fall to the bottom of the cells. This action can take place in a relatively short length of time. Accordingly, the trickle charger should be carefully set as per the battery manufacturers recommendations for the ambient temperature and operating conditions present. It is recommended that the trickle charger be run from a regulated line source if available. The generator or battery charger attached to the engine generator set should have an automatic charging-rate regulator or have the charging rate correctly adjusted for the average engine-starting frequency and average running time so as to replace the charge dissipated in the starting operation.

Alarm Contacts. An auxiliary contact shall be provided on the transfer panel which will close upon operation of the transfer switch for the purpose of activating a remote alarm.

Test Switch. A test switch, appropriately marked, shall be provided to simulate a normal source failure. The switch shall affect the control circuit only and shall have two positions—one to run the stand-by unit without transferring, and one to achieve actual transfer of load to the stand-by unit. When operating the engine without intending transfer of the load, a failure of the primary source will still cause normal transfer. When actually transferring the load, the transfer will take place with no greater than 1/4-second interruption of power to the load. The transfer back to primary source will take place automatically in normal fashion and timing as specified. The test switch shall be a momentary type that cannot be left in the test position.

Housing. The transfer panel shall be furnished with suitable terminals clearly marked for all external connections. It shall be for wall-mounting and enclosed in a National Electrical Manufacturers Association type-1 cabinet (or equivalent) with a gasketed dust-tight cover.

OTHER ELECTRIC CONTROLS

Emergency Stop Switch. The stand-by power unit shall be designed to accommodate a remote, wall-mounted 2-position switch for stopping the engine in an emergency. The circuit shall be such that, once stopped by the emergency stop switch, the engine will not attempt to restart automatically until the emergency switch is returned to normal position.

STANDARD ACCESSORIES

Each standby power set shall be supplied with the following standard accessories:

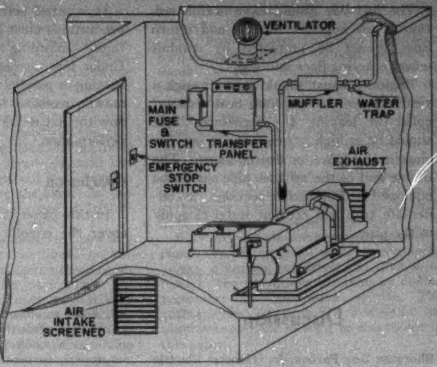
1. Starting battery of voltage and ampere-hour capacity recommended by engine manufacturer but, in every case, capable of cranking the unit at the recommended cranking speed for a period of 5 minutes at temperatures above 32 F. Batteries shall be shipped dry-charged with electrolyte included.
2. Underground fuel tank not less than 55 gallons for a 5-kw plant or 110 gallons for a 10-kw plant. Tank fittings to include suitable combination filler and vent pipe (with locking-type cap) not less than 30 inches long to allow use of measuring stick. Tank will include fitting for gas supply and return line from day tank. Tank must be suitable for direct burial.
3. Radio-noise suppression kit consisting of shielded ignition wires, caps over spark plugs and condensers shall be installed in standard equipment.
4. Special tools required for installation or normal maintenance, including a hand crank.
5. Wiring diagram installation, operation, and maintenance instructions; certified dimensional installation drawings; shipping list; and renewal parts lists.

OPTIONAL ACCESSORIES

The following accessories shall be available when needed:

1. Line ammeter and voltmeter (with meter switches if desired).
2. Vibration isolators.
3. Metal housing enclosure with removable side panels.
4. Meter-type fuel gauge.
5. Low fuel supply alarm (independent contacts to close at preset fuel level).
6. Liquid petroleum gas accessories: primary regulators, fuel preheaters, metering equipment, fuel lines, and connectors.
7. High rate position on trickle charger capable of replacing 1/2 ampere-hour capacity of the battery in 24 hours.
8. Overvoltage protection transfer operation (similar to low voltage function).
9. Automatic regulator on the engine-driven generator or battery charger to give optimum charge rate depending upon battery charge.
10. Extra-long-life lead acid or alkaline starting batteries.
11. Automatic exerciser timing unit for periodic stand-by unit operation. (A minimum of 30 minutes each week is recommended.)
12. Cathodic protection on fuel tank.

Fig. 3. Recommended installation stand-by engine generator



13. Engine crankcase or cooling-liquid heaters.

Installation Notes

The manner in which the stand-by unit is installed is an important factor in its reliability in microwave service. Fig. 3 shows a plan for installation which is recommended by engine generator and microwave equipment manufacturers. Following are comments on installation based on users experience and manufacturer recommendations:

A separate enclosure for the engine generator set is desirable from a safety, temperature rise, and noise point of view. The exit from the building should not be through the engine enclosure. The emergency stop switch should mount at the entrance to the engine room.

Pusher-type engine fans are recommended for exhausting engine-cooling air through fireproof ducts to the outside. This positively exhausts dangerous engine exhaust gases that have escaped. It also runs the heated air outside, preventing recirculation of air in building which tends to raise inside temperature rapidly.

Exhaust-ducting, and air inlet and outlet ports must not create too great a pressure drop or back pressure so that normal cooling-air volume is reduced. Caution should be taken to avoid locating in positions where prevailing drafts or winds interfer with normal air intake or outlet. Ports should be located so that they will not be blocked by snow, leaves, mud, etc.

The stand-by unit house must be ventilated and/or insulated to keep ambient within rated temperatures of −20 and +125 F. Batteries, relays, dry rectifiers, and other components fail rapidly beyond these limits and the manufacturers warranty will not apply. Batteries at low charge begin to freeze at about −20 F but, at full charge, the freezing point is much lower. When temperatures above 100 F are usual, lower specific gravity batteries will give better service.

In cold weather, water-cooled radiators must be protected against freezing. Some users report difficulty with ethylene glycol antifreezes penetrating into the lubrication oil and gumming or binding the pistons of the engines so that they will not start after an idle period.

In installing fuel lines, care must be exercised not to exceed the 8-foot lift ability of the fuel pump and to use large enough fuel lines on long runs to avoid excessive friction loss. The return line from the day tank to the fuel tank should terminate under the fuel surface to prevent an air circulation through the day tank to the vent. This would allow excessive evaporation of the gas from the day tank. The filler piper should discharge at bottom of fuel tank to prevent agitation of surface level on filling.

In installing engine, mount on raised base to facilitate draining oil and placement of drip pans beneath engine. A surrounding dike is desirable to confine spilled or leaking fuel. A 24-inch working space is desirable on all sides of engine.

The fuel tank should be installed underground with a minimum of 24 inches of fill over the tank. Where it is installed in wet soil, the tank should be weighted with stone or concrete to prevent its surfacing through its own buoyancy. The fuel tank should be provided with at least a 2-inch fill line with removable screen and locking cap, and a vent line with breather cap. These lines should extend well above possible snow or water line.

The fuel line should have flexible section at the engine. All fuel and return lines should be protected by conduit where entering floor and walls.

Engine exhaust should pass through a weatherproof, rodentproof, heat-resistant collar in leaving the structure. Exit should be as high as necessary to prevent clogging by fallen or drifted snow. The engine end of the exhaust pipe should be equipped with a flexible section. A condensate trap will prevent water-clogging of the pipe.

In liquified petroleum gas installations precautions must be taken to install fuel tanks according to local regulations. Under low temperature conditions, preheating or parallel manifold arrangements may be necessary to keep gas pressure and flow to that required by engine for rated performance.

Conclusion

In this paper it was not attempted to cover the equally important subject of operational maintenance since that is extensive in itself and warrants a separate discussion. The material presented does clearly indicate the necessity of obtaining and correctly installing engine generators sets well suited to the purpose intended.

◆

Discussion

Sherman Guy Forbes, Jr. (General Electric Company, Beaumont, Tex.): The paper fails to consider the one determinant that will assure reliable operation of emergency power plants using piston-type internal combustion engines as prime movers. That important ingredient of reliability is maintenance. By neglecting this important matter it fails to justify recommending specialized engine-generator sets for stand-by service in microwave communication systems.

Maintenance includes operating conditions and methods, and the type and quality of the upkeep given the individual components that make up an emergency power plant. These vital matters must be among the items considered fully to allow correct application of an engine-generator set as a part of an emergency power plant that will be dependable. If their vital importance is not weighed heavily, the best and most specialized engine-generator set will have have no reliability.

There are in reality three separate and distinct operating and maintenance problems, rather than one. The three are determined by: The engine and its auxiliaries; the generator and its auxiliaries; and the controls that make the engine-generator set a stand-by or emergency power plant.

Given the consideration due their individual peculiarities, it would appear that the basic engine-generator set can be a standard unit. Then a special unit of high cost due to small-quantity production and of dubious worth with regard to improvements in reliability will not be required.

The prime mover in either a standard or special engine-generator set will normally determine the over-all reliability of the emergency power supply. The types of sets in question employ piston-type internal combustion engines as their power source. In all such engines operating reliability is determined by the operating conditions and the upkeep of the engines. Thus these vital matters must definitely be among the items considered to allow correct application of an engine-generator set for emergency service on a microwave communications system. If they are not considered, the best and most specialized engine-generator set will have no reliability.

Without further delving into the operation and maintenance of the power plant, it is advisable to consider other subjects in the paper that affect the reliability of the power plant as a whole and which appear to be improperly correlated.

In the section entitled "Ordering and Performance Specifications" are itemized separately many conditions that cannot be so considered. Under the subtitle "Engine" duty, ambient temperature, relative humidity, and governor control should all be considered as a single item. The information about all of these is required to determine the real duty cycle and thereby the size of the engine required. Under the subheading "Alternator" specifications are set for the voltage regulation for 20% load variation occurring at a frequency of 40 cycles per minute. This disagrees markedly with the 50% load variation called for in the discussion of governor control. It is in the subsection "Frequency Regulation" that the allowable speed variation is established for the engine under the load swings given in the previously mentioned paragraphs. Furthermore, the description of the duty of the engine, and its governor control are contradictory. The first establishes a requirement for a continous rated load and the second a load that is continually varying in increments of 50 per cent (%) at an unspecified rate. In other words, during the daylight hours when the beacon is not operating full load will be but 50% of rated. This then affects what is said about relative humidity. It is stated that full load is required for reliable engine operation at high relative humidities. Finally, the engine is required to go from standstill to full load in less than 30 seconds.

Rather than break down all the engine specifications item by item, the specifications should establish the load, the duty cycle, and the special conditions of operation. These then can be used to determine the other conditions that must be met.

The paper indicates a preference for liquid-cooled engines. Such engines cannot successfully meet the rapid-start and load assumption requirements previously called for. This is because of the thermal inertia of the cooling system associated with a liquid-cooled engine. In addition, a liquid-cooled engine calls for the maintenance of a third fluid system not required with an air-cooled engine.

Where ambient temperatures permit, a liquified petroleum gas should be used as a fuel as these fuels minimize crankcase dilution, carbon deposits in the firing chambers, decomposition of the lubricating oils from chemical reactions with condensates in the crank case, wash-down of lubricating oils from the cylinder walls during starts, and starting difficulties after long periods of idleness.

It is felt that proper specifications covering operating requirements for the set must be established so that a good application can be made. Then specific operating conditions such as ambient temperatures, relative humidity, and altitude should be set up in each case in order to determine the variations of the basic set required to meet definite local conditions. With all of this specified, adequate operating and maintenance schedules can be established that will allow such sets to be truly reliable.

Nelson B. Tharp: As Mr. Forbes points out, maintenance is an important "ingredient of reliability," so much so, in fact, that the author clearly stated in the paper's conclusion that no attempt had been made to include it in this paper since to be adequately covered, it should be the subject of another paper. The fact that it was not included, however, does not in the author's mind "fail to justify recommending specialized engine generator sets for stand-by service in microwave communications systems" as Mr. Forbes states. One must purchase and install equipment before he can maintain it, and no amount of maintenance, however thorough, will overcome inherent shortcomings of misapplied equipment. The many users of engine generator sets in microwave services would object to the idea that their troubles have all been due to their poor maintenance work. The "special unit at high cost," appears to be contrary to the opinion of various engine generator manufacturers who were an integral part of the Radio-Electronics Television Manufacturers Association Committee and to the author's experience in purchasing units which meet the requirements.

With respect to the comments on the numerical arrangement of the material, it is true that a number of other arrangements could have been employed, possibly with some improvement in organization.

Mr. Forbes indicates a contradiction between the paragraphs on governor control and voltage regulation with respect to performance under varying loads. It should be noted that for voltage regulation it is required that the output voltage remain within 5% of rated voltage at load variations for 20 to 100% and specifically includes a 20% variation occurring at 40 cycles per second (beacon load). The comment on governor control (not the specification) merely points out that if the governor meets the requirements with respect to transient loads as specified for voltage regulation, even a 50% load variation from a flashing beacon will not affect the generator output to where it would interfere with normal microwave operation.

Mr. Forbes feels that there is conflict between the paragraph on duty in the section "Engine" and the one on governor control because one deals with steady loads and the other with transient loads. Both types must be considered since the engine generator will be expected to perform correctly under both conditions. Again, for governor control, the item does not set up a 50% flashing load requirement, but merely comments on the ability of the engine to do this if it meets the other transient requirements in the paragraph.

It is desirable for the engine to start and assume normal load in 30 seconds since the microwave users wish to reduce service outage to a minimum and this is the shortest reasonable time at −20 F. Some sad experiences have shown that there may be a significant difference between the time that an engine achieves rated speed and the time that it will assume rated load. Sometimes an engine will reach speed quickly, but when the load is applied will slow down to where it will fail to carry the load. In this case a warm-up period is required, resulting in delay in microwave service.

The paper was not intended to show any preference with respect to liquid or air-cooled engines. Its only purpose was to set up the engine generator performance requirements for adequate microwave service, and to comment on certain facts which may be of interest or value to a user. As long as an engine meets the requirements as set up by the microwave needs, choice of cooling is strictly the user's preference.

Mr. Forbes states that where ambient temperatures permit, liquified petroleum should be used. Although the author is inclined to agree with this statement and its supporting reasons, it was not felt that a paper of this nature has the right to say what type of power should be used, but rather should only describe what performance is necessary for adequate microwave service, and present facts on the characteristics of each various types of power sources so the user can choose for himself in the light of his particular situation.

It is hoped that someone will prepare a paper describing good maintenance techniques, operating problems, and their solutions in the operations of stand-by engine generators in microwave service. The author wishes to thank Mr. Forbes for his comments and the interest he has shown in this paper.

Fundamental Relations of System Voltage Drop and System Loads

G. M. MILLER

L. W. ROBBINS
ASSOCIATE MEMBER AIEE

ONE of the primary requirements of modern electric power systems is to deliver power to the loads at essentially constant voltage. With strong emphasis on fulfilling the voltage requirement, some of the important factors which affect the ability of the over-all system to deliver power are overlooked. A simple series circuit including a constant-voltage source, a series impedance, and a load impedance displays characteristics that are similar to those of an over-all electric power system. In this paper, it is explained how some of the fundamental concepts derived from a simple series circuit may be used to show the interrelations between voltage drop and load-carrying ability of a system. A clearer understanding of the factors which influence the ability of a system to deliver power will enable the engineer to plan system development and operation to make the most effective use of lines and transformers to deliver power from generation to the load.

Curves of voltage drop plotted against power delivered at constant power factor have been used for studying performance of a line section.[1,2] By considering an over-all power system as a single series impedance, similar curves give useful information on the ability of a system to deliver power at satisfactory voltage. A series circuit having a 1.0 per-unit (pu) constant-voltage source, 1.0 pu series impedance, and a static-impedance load gives general curves that may be adapted by a pu approach to estimate performance of a power system. Examples of the application of this method to an idealized system are presented to show the use of these general curves.

Conclusions

The general curves of voltage drop and power delivered through 1.0 pu impedance applied to electric power systems show the effect of such factors as the following:

1. The maximum power that can be transmitted through a power system depends on the total impedance of the system between generation and load, the resistance-reactance (R/X) ratio of the total system impedance, and the power factor of the load.

2. Supplying kilovar requirements of system load locally and power-factor improvement practices not only reduce the voltage drop in a power system but also increase the maximum power the system can deliver. An example shows that correcting load power factor from 0.8 to 1.0 more than doubles the maximum power the system being studied could deliver for a given voltage drop.

3. Convenient comparisons between normal and line-outage conditions can be made from the general pu curves by reference to different kilovolt-amperes (kva) bases determined from the total system impedance for each condition.

4. The use of several load tap-changing transformers or regulators in series can increase the maximum power a system is able to deliver at satisfactory voltage. Analysis using the general voltage-power curves provides a convenient method for comparing how effective additional regulating range or power-factor correction will be on a specific system.

Assumptions

The following general assumptions were made for this analysis:

1. The analysis is limited to steady state conditions.

2. Loads are represented by static impedances and are assumed to have constant kilowatt characteristics. This is the same assumption as made for a-c network-analyzer studies of load and voltage problems.

3. Synchronous stability problems are not considered. Where steady-state stability between synchronous machines is a problem, the stability limits may restrict power transfer to less than indicated by the voltage limits developed from this analysis.

4. Line-charging has been neglected in the general analysis. This gives more conservative results than would be obtained if appreciable amounts of line-charging capacitance were included.

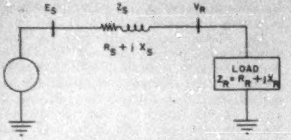

Fig. 1. Simplified equivalent circuit

5. In the application to actual systems it is assumed that adequate capacity is provided to avoid thermal limitations in components such as transformers, line conductors, and switches.

Explanation

The simple series circuit shown in Fig. 1 is made up of a source of constant voltage E_s, a system impedance Z_s, and a variable load impedance Z_r. If the load impedance is gradually reduced from some very high value, keeping power factor constant, the power received P_r increases and the load voltage V_r drops below E_s. The power increases up to a maximum and, if the load impedance is further reduced, the power received decreases until it reaches zero when the load impedance reaches zero. With E_s 1.0 pu volts and Z_s 1.0 pu reactance, Fig. 2 shows the load power and voltage as Z_r is reduced, keeping power factor constant. These curves may be calculated by solving equations 2 and 10 by longhand calculation, graphically by circle diagram, or by using the a-c network analyzer.

The point of maximum power is of some special interest. By letting k represent the ratio X_r/R_r, or the cotangent of the load power-factor angle, it is shown in Appendix I that the maximum power at a given power factor is delivered when $R_r = Z_s/\sqrt{1+k^2}$. Since k may vary, it is also shown that the greatest maximum power is delivered when $k = -X_s/R_s$ or when $R_r = R_s$ and $X_r = -X_s$. Adjusting the load impedance to equal the complex conjugate of the source impedance will be recognized as impedance-matching, as used frequently in communication and other low-power circuits. The application of impedance-matching to the fullest extent is impractical on constant-voltage power systems, but limited application of the same general principle can be made to use more effectively the capability of a system to transmit power from source to load.

The fundamental equations for power flow through impedance show that the power received at the load depends not only on the load impedance but also on the magnitude and R/X ratio of the system impedance. To cover the range of constants ordinarily encountered in electric utility systems, this analysis has been made covering system impedance R/X ratios from 0 to 0.4, and covering load power factors from 0.8 lagging to 0.98 leading.

Curves of load voltage and power received at constant power factor provide a convenient method to show the relation between system load-carrying ability, power factor, and voltage drop. Curves for loads at power factors of 0.8, 0.9, 0.98, 1.0 and 0.98 leading supplied from 1.0 pu voltage through 1.0 pu system impedance are plotted for system R_s/X_s ratios of 0 in Fig. 2, 0.1 in Fig. 3, 0.2 in Fig. 4, 0.3 in Fig. 5, and 0.4 in Fig. 6.

To show how system R/X ratio affects the ability of a system to deliver load at satisfactory voltage, a constant-voltage line A is shown on each family of curves at 0.825 pu volts. This particular value is used later in the section entitled "Example 1." It is based on the assumption that the transformer turn-ratios and the regulating range available in the system can provide rated voltage to the load as long as the pu voltage is not lower than 0.825 pu. Table I shows the maximum 0.8 and 1.0 power-factor loads the system can deliver at this voltage over the range of system R/X ratios from 0 to 0.4. Similar comparisons could be made at any other pu voltage or at other power factors.

Pu Approach

By special application of the pu system, one set of curves calculated for a source voltage E_s of 1.0 pu and a system impedance Z_s of 1.0 pu can give practical results for any power system that can be reduced to an equivalent of the simple series circuit shown in Fig. 1. Application of the method to study over-all system performance is described here, but it is equally applicable to the part of a system that is fed from a constant-voltage source. If the source voltage cannot be held constant, it is necessary to go farther back into the system until a source point is found where voltage can be maintained constant over the desired range of loads. Failure of the assumed source to maintain constant voltage would introduce sizeable errors in the maximum power delivered by the system.

When the pu system is used for system studies, a base kilovolt (kv) is usually chosen to correspond to operating voltage and a free choice of base kva can be made at any convenient number, like 50,000 or 100,000 kva. Base current and base impedance are dependent on base kv and base kva, as shown in Appendix II. For application of the pu curves, Figs. 2 through 6, to actual systems, the operating voltage at source E_s is chosen as base kv. The base kv at other voltage levels is then determined by the actual transformer turn-ratios. The most significant change from the usual procedure is to choose a base kva that will make the total system impedance Z_s equal to 1.0 pu.

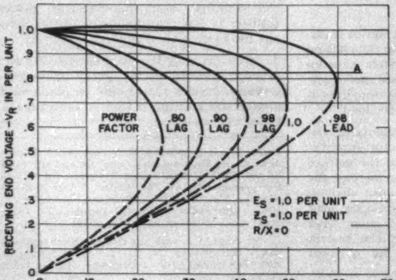

Fig. 2 (left). Receiving - end voltage and power received at constant power factor with system ratio R/X=0

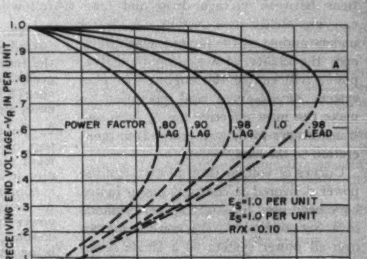

Fig. 3 (right). Receiving - end voltage and power received at constant power factor with system ratio R/X=0.10

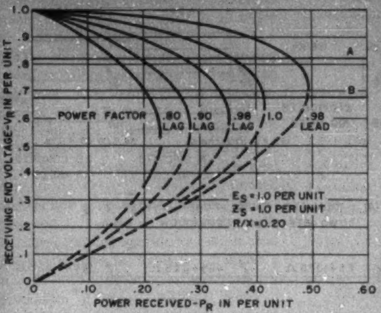

Fig. 4 (left). Receiving-end voltage and power received at constant power factor with system ratio R/X=0.20

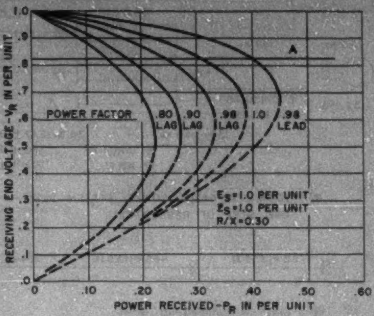

Fig. 5 (right). Receiving-end voltage and power received at constant power factor with system R/X ratio=0.30

Base kva is made dependent on system impedance and base kv. If the system impedance is changed, a different base kva is used. Comparisons between different systems are made in kilowatt power received rather than in pu, because the pu values are on different base kva.

Application

Several examples will demonstrate use of the pu curves to reach the general conclusions already stated.

EXAMPLE 1

A simple radial system having generation at one location, 138-kv transmission lines, 34.5-kv subtransmission, and 7.2/12.47-kv distribution is shown in Fig. 7(A). The transformer turn-ratios are chosen so that at no load a generator voltage 5 per cent below generator rating of 13.8 kv will give 138 kv on the transmission lines, 34.5 kv on the subtransmission, and 12.47 kv on the distribution system with the regulating transformer at the 34.5 to 12.47-kv step-down on its neutral position. The only load tap-changing equipment in the entire system is located at the 34.5 to 12.47-kv substations and has ±10-per-cent range available for regulating the 12.47-kv distribution system. For this example it is assumed that half of this regulating range is reserved to correct for contingencies giving higher than normal voltage at the primary side of these substations.

Since this simplified system is symmetrical, it can be easily reduced to a single equivalent impedance that will represent the entire system from the source of regulated voltage at the generator terminals to the load appearing at the primary of the distribution transformers out on the 12.47-kv feeders. The steps in the reduction of the system, conversion to pu, and finding the total system impedance are shown in Figs. 7(B) and (C). Since conditions of maximum load are to be considered, it is assumed that the generator voltage at peak load will be held at 14.5 kv, 5 per cent above generator rating of 13.8 kv. The generator operating voltage of 14.5 kv is chosen as base kv. The base kv for each of the other voltage levels is determined by the transformer turn-ratios from that base. It is assumed that 100,000 kva of transformer capacity is used at each transformation. The impedance for each part of the system is calculated in pu on a 100,000-kva base and the appropriate kv base. The base kv and the pu impedance for each part of the system on 100,000 kva are shown in Fig. 7(C). The total pu impedance for the system is $0.104+j0.4949$ pu or 0.506 pu on 100,000-kva.

By changing to a new kva base that will make 0.506 pu on 100,000 kva equal to 1.0 pu, the general curves calculated for 1.0 pu system impedance become directly applicable to the system being studied. Appendix II shows the derivation of the following expression for changing to the new base kva.

$$\text{base kva}_2 = \frac{\text{base kva}_1}{Z_1 \text{ in pu}}$$

$$\text{base kva}_2 = \frac{100{,}000}{0.506} = 197{,}500 \text{ kva}$$

The R/X ratio of the system impedance is 0.104/0.495 or 0.21. Since this is very close to 0.20, the curves in Fig. 4 will be used for this case.

The base kv for the 12.47-kv system established by the generator base kv and turn-ratio is 15.1 kv when the regulating

transformers at the 34.5 to 12.47-kv substations are at maximum boost. Normal operating voltage of 12.47 kv is 0.825 pu, and it can be plotted in Fig. 4 as a horizontal line *A*. The intersection of this voltage line and the constant power-factor curves designates the maximum power that can be delivered at 12.47 kv at that power factor.

Evaluation of the power received shows that 28,800 kw can be delivered at 0.8 power factor, and 69,500 kw can be delivered at 1.0 power factor. For this system, power-factor correction from 0.80 to 1.0 more than doubles the amount of revenue-producing kilowatts the system can deliver.

Example 2

An example of practical interest is to determine the maximum load the simplified system of Example 1 could deliver with one of the 138-kv transmission lines out of service. The impedance of the 138-kv line is doubled to represent the loss of one line, and the total system impedance becomes $0.1365+j0.658$ pu or 0.672 pu on 100,000 kva. The base kva to make this impedance 1.0 pu is 149,000 kva. The system R/X ratio is 0.207 so the curves in Fig. 4 will again be used. The total regulating range is the same as was available in Example 1 so the same voltage line will be used.

With one 138-kv line out of service, the system can deliver 0.348 pu power on a 149,000-kva base or 51,800 kw at unity power factor. This compares with 69,500 kw at unity power factor when both lines were in service. At 0.80 power factor, 0.146 pu power can be delivered, which is 28,800 kw for the normal condition and 21,800 kw when the line is out.

Example 3

If the system used in Example 1 has load tap-changing equipment at the 138/34.5-kv transformation as well as the 34.5/12.47-kv substations, the results will be somewhat different. The system using two steps of regulation is shown in Fig. 8(A). The transformer turn-ratios are chosen so a no-load generator voltage 5 per cent below rating of 13.8 kv will give 138 kv on the transmission lines, 34.5 kv on the subtransmission lines with the 138/34.5-kv transformer tap-changers on maximum buck, and 12.47 kv on the distribution feeders with the 34.5/12.47-kv transformers on the neutral tap position.

The steps in the reduction of the system, conversion to pu, and finding the total system impedance are shown in Figs. 8(B) and (C). The generator operating voltage is chosen as base kv and is assumed to be 14.5 kv under maximum load conditions. At maximum load, the 138/34.5-kv transformers are assumed to be on maximum boost tap of 113/34.5 kv, and the 34.5/12.47-kv transformers are assumed to be on maximum boost tap of 34.5/13.72 kv. These turn-ratios give the new base kv, shown in Fig. 8(C). As in Example 1, it is assumed that 100,000 kva of transformer capacity is installed at each transformation. Fig. 8(C) shows the impedance of each part of the system calculated in pu on 100,000 kva and the proper kv base, as determined by actual turn-ratios. The total pu impedance for the over-all system is $0.0817+j0.4097$ or 0.418 pu on 100,000 kva.

The system impedance of 0.418 pu on 100,000 kva is equal to 1.0 pu impedance on a 239,000-kva base. Its R/X ratio is 0.20 so the curves in Fig. 4 apply.

The base kv for the 12.47-kv part of the system is 18.4 kv as determined by the base kv at the generator and the assumed turn-ratio. Normal operating voltage of 12.47 kv is 0.678 pu on the 18.4-kv base. A constant voltage line *B* is plotted in Fig. 4 at 0.678 pu volts. The intersection of this line and the constant

Power-factor curves show the maximum Power that can be delivered at 12.47 kv for that power factor.

The effect the second tap-changing transformation has on the load-carrying ability of the system is shown by a comparison with the results of Example 1. The results are tabulated in Table II.

The effect an additional regulator has on raising the maximum power delivered depends on where the regulator is located and on how much of the total system impedance it changes to a higher base kv. However, on any specific system, a comparison similar to Table II provides a sound basic approach for studying the economics of using additional steps of regulation or power-factor correction to raise the load-carrying ability of that system.

Summary

These three examples illustrate use of the general voltage-power curves to estimate over-all system performance. The pu approach makes it possible to obtain results on a variety of systems from one set or curves derived from a series circuit having a 1.0 pu voltage source and a 1.0 pu system impedance. The general curve and the pu approach provide a useful method for studying over-all system performance and comparing alternate plans or apparatus in planning for future system growth.

Appendix I. Calculation of Curves

In the series circuit, Fig. 1, E_s represents a source of constant voltage, Z_s represents the total system impedance, and Z_r represents the load impedance. The maximum power that can be delivered through a given transmission system or source impedance can be found by expressing the power received in terms of known parameters and solving for the maximum with respect to Z_r.[2]

The current in the series circuit is expressed as

$$I=\frac{E_s}{\sqrt{(R_s+R_r)^2+(X_s+X_r)^2}} \tag{1}$$

The power received at the load is

$$P_r=I^2R_r=\frac{E_s^2R_r}{(R_s+R_r)^2+(X_s+X_r^2)} \tag{2}$$

To find the maximum power that can be delivered at a given power factor, let k represent the cotangent of the power-factor angle or the ratio of X_r/R_r

$k=X_r/R_r$

$X_r=kR_r$

Substituting in equation 2

Table II. Comparison of Results

Load Power Factor	Power Delivered System Using One Load-Tap Changing Transformation, Kw	 System Using Two Load-Tap Changing Transformations Kw
0.8 lagging	28,800	50,200
0.9 lagging	37,500	63,900
0.98 lagging	52,900	82,000
1.0	70,100	99,500
0.98 leading	91,300	*

*This point is below the voltage at maximum power so the full tap range cannot be effectively used.

$$P_r=\frac{E_s^2R_r}{(R_s+R_r)^2+(X_s+kR_r)^2} \tag{3}$$

With k held constant to represent constant power-factor load, the value of R_r that will give maximum received power is found by taking the first derivative of P_r with respect to R_r and equating it to zero. Then, solving for R_r gives

$$R_r=\frac{\sqrt{R_s^2+X_s^2}}{\sqrt{1+k^2}}=\frac{Z_s}{\sqrt{1+k^2}} \tag{4}$$

This value of R_s in terms of Z_s and k is substituted in equation 3 and after expanding and simplifying gives

$$P_{r\ \max}=\frac{E_s^2}{2Z_s\sqrt{1+k^2}+2(R_s+kX_s)} \tag{5}$$

Since k may be variable, it is also desirable to find the value of k which gives the greatest maximum power received. This is done by taking the first derivative of $P_{r\ \max}$ with respect to k, equating it to zero, and solving for k. This gives

$$k=\pm\frac{X_s}{R_s} \tag{6}$$

The greatest maximum power received is found by substituting equation 6 in equation 5.

$$P_{r\ \max\ \max}=\frac{E_s^2}{4R_s+\frac{2}{R_s}(X_s^2\pm X_s^2)} \tag{7}$$

By inspection, this expression of received power will have its maximum value when $k=-X_s/R_s$ and equation 7 becomes

$$P_{r\ \max\ \max}=\frac{E_s^2}{4R_s} \tag{8}$$

For $k=-X_s/R_s$, the X_s term will have to be the negative quantity. When these conditions are met

$$R_r=\frac{\sqrt{R_s^2+X_s^2}}{\sqrt{1+X_s^2/R_s^2}}=\frac{R_s\sqrt{R_s^2+X_s^2}}{\sqrt{R_s^2+X_s^2}}=R_s \tag{9}$$

Since by definition $k=X_r/R_r$ and for greatest maximum power received $k=-X_s/R_s$ and $R_r=R_s$, then $X_r=-X_s$ or $X_s=-X_r$. Therefore, the system and load impedances are equal and the reactive components have opposite signs, or the load impedance and the system impedance are the complex conjugates of each other.

The voltage at the load is of primary interest in constant-voltage electric power systems. It can be calculated

$V_r=E_s-IZ_r$

In phasor form

$$I=\frac{E_s}{R_s+R_r+j(X_s+X_r)}$$

and

$$V_r=E_s\left(1-\frac{R_s+jX_s}{R_r+R_s+j(X_s+X_r)}\right) \tag{10}$$

$$V_r=E_s\left(\frac{R_r+jX_r}{R_r+R_s+j(X_s+X_r)}\right)$$

Appendix II. Calculation of Base Kva and Base Current

In balanced, 3-phase systems, the relations between system quantities in ohms, amperes, volts, and corresponding pu quantities are given by the following equations

base kva = base current, amperes $\times\sqrt{3}$ base line-to-line kv

base current, amperes =

$$\frac{\text{base kva}}{\sqrt{3}\ \text{base line-to-line kv}} \tag{11}$$

base impedance, ohms =

$$\frac{\text{base line-to-line kv}\times 1{,}000}{\text{base current}\times\sqrt{3}}=\frac{(\text{base line-to-line kv})^2\times 1{,}000}{\text{base kva}} \tag{12}$$

$$\text{pu } Z=\frac{\text{actual } Z,\text{ ohms}}{\text{base impedance}}$$

$$\text{pu } Z=\frac{\text{actual } Z\times\text{base kva}}{(\text{base line-to-line kv})^2\times 1{,}000} \tag{13}$$

From equation 13, the following expression for changing pu impedance from one kva base to another or from one kv base to another is apparent

$$\text{pu } Z_2=\text{pu } Z_1\left(\frac{\text{base kva}_2}{\text{base kva}_1}\right)\left(\frac{\text{base kv}_1}{\text{base kv}_2}\right)^2$$

Rearranging

$$\text{base kva}_2=\text{base kva}_1\left(\frac{\text{pu } Z_2}{\text{pu } Z_1}\right)\left(\frac{\text{base kv}_2}{\text{base kv}_1}\right)^2 \tag{14}$$

Equation 14 may be solved to find a new base kva that will make the pu impedance on the old base kva equal to 1.p pu on the new base. Assuming no change in base kv, the equation is simplified to

$$\text{base kva}_2=\frac{\text{base kva}_1}{\text{pu } Z_1} \tag{15}$$

Discussion

H. R. Tomlinson and R. O. Bigelow (New England Power Service Company, Boston, Mass.): The authors have provided system planners with an interesting approach for estimating, on an over-all system basis, the voltage performance of alternate methods of system expansion. This method appears applicable in those cases where voltage conditions alone are the determining factor in establishing maximum permissible line loadings; and where sufficient accuracy can be obtained by reduction of the system constants to a single lumped impedance. It seems likely that these restrictions may result in very limited applications of the method or in erroneous conclusions from a study of alternates if the limitations of the method are unintentionally exceeded.

In the first place, the practical problems of system planning invariably involve a combination of thermally limited and voltage-limited facilities which are closely interrelated. Furthermore, the importance of the thermal limitations is greatly increased as voltage-improving devices such as regulators or capacitors are installed on the system. It does not seem practical, therefore, to eliminate this interrelationship as suggested by the authors' assumption 5. Strong emphasis should not be placed on voltage requirements without giving equal consideration to the importance of delivering power within thermal limitations and with losses based on optimum design. As an example, one conclusion which might be drawn from a study based on the power-versus-voltage curves of the paper is that an increase in load capability of a system can be provided more economically with voltage-regulating equipment than with shunt capacitors installed at the locations of reactive load. This appears by comparing an investment in regulating equipment with an investment necessary for shunt capacitors to provide the same increase in load capability. Although this result verifies the fact that strictly voltage limitations can be alleviated more economically with regulating equipment than with capacitors, it completely excludes both the increased load capability provided by capacitors in thermally limited elements of the system and the reduction in losses in all elements of the system back to the source of supply. These added factors will generally be predominantly favorable to the capacitor alternate.[1]

Secondly, the method requires that the entire system be reduced to a single lumped impedance. This means that any studies based thereon must be limited to consideration of only two points on the system. In the examples given in the paper, the authors concentrate their attention on a source, either the generator terminals or some other bus, where constant voltage is maintained, and on an effective center of distribution where the load is assumed to be concentrated. No consideration is given to the intermediate substation bus voltages or gradients on intervening lines having widely different R/X ratios. Again, considering the method from the point of view of application to practical system design problems, there are very few cases were conditions at these intermediate points can be neglected.

A good example is a typical distribution feeder having a voltage gradient between the first and last customer. The application of additional regulating equipment will permit heavier loading for the same center-of-distribution voltage but there will be a steeper voltage gradient which may exceed permissible voltage limits at the extreme ends. When this type of approach is extended to include the entire supply system, it is necessary to retain, in the equivalent representation, the identity of important intermediate points between the source and the load. This is particularly true on large systems where a significant portion of the load may be delivered at transmission or subtransmission voltages. In addition, the lumped impedance approach provides no means of including diversity or of establishing which portions of the system are voltage-limited and which portions are thermally limited.

To summarize, we concur with the authors' conclusion that the use of capacitors and voltage regulators will pay large dividends by increasing permissible loadings with continued acceptable voltage service. It is also evident that the generalized curves presented in this paper provide a very useful tool for estimating purposes on those portions of a system where voltage conditions can definitely be established as the only limiting factor and where intermediate points are of no concern.

It appears questionable, however, whether this technique can be applied successfully to an entire system from generator to load, as suggested by the authors in their illustrative examples. It is recognized that general studies of this type must be based on simplified equivalents if the complexity of the mathematics is to be contained within reasonable bounds. It is equally important, however, to realize that the value of the results obtained are entirely dependent upon the accuracy with which this equivalent represents actual system conditions. It is our opinion that application of this method on such a broad scale requires an oversimplification which may lead to serious error.

REFERENCE

1. AN EVALUATION OF POWER-FACTOR CORRECTION ON A SYSTEM BASIS, H. R. Tomlinson, R. O. Bigelow. *AIEE Transactions*, vol. 73, pt. III, 1954 (Feb. 1955 section), pp. 1,677–84.

G. M. Miller and L. W. Robbins: We certainly agree that many of the details have not been included in the examples of the paper. We wonder, however, if these details are ever handled completely when projecting the system into the future, say, as far as perhaps half the life of the system being built today. At that time, the system load will be two or four times today's load. Will the increased load be carried simply by duplicating today's system or will some of the increased load be carried on today's system. Certainly, decisions made now will affect what can be done in the future. Perhaps the idealized system approach is one method of answering these questions.

Mr. Tomlinson and Mr. Bigelow very accurately pointed out that there are two ways in which comparisons can be drawn from the curves of the paper. One is the comparison between regulating equipment and power-factor improvement equipment to handle the same kilowatt load. The second comparison concerns the amount of loading that can be handled within a given system voltage pattern. It should be noted that these two comparisons correspond to a vertical and horizontal comparison respectively on the curves of Figs. 2 through 6. We agree that losses and thermal loading should be part of the engineering evaluation of the first comparison. Actually, we have found the approach of the paper particularly useful in evaluating losses for various system patterns.

In the second comparison we would like to point out one method that might be used to factor in the effect of thermally limited equipment when considering increased loading within a given system voltage pattern. We may use the first example of the paper whose total transformer impedance represents very nearly 40 per cent of the total impedance between generation and load. Normally, transformers are applied on a thermal basis and transformer bank sizes would be expected to increase proportionally to the increase in load permissible with power-factor improvement. This would result in a decrease of transformer impedance proportional to the reciprocal of the increase loading. Actually, this results in an even larger increase in the loading of the remainder of the system than is indicated in Table I. Referring to line *A* of Fig. 4, it is seen that power transmitted at 0.98 lag equals 0.27 pu and the power transmitted at 0.98 lead equals 0.46 pu. The new system reactance at 0.46 pu loading would be equal to 0.6 + 0.27/0.46 × 0.4 or 0.824 of the original system reactance. However, the 0.46 pu loading is on the new system base and corresponds to 0.46 × 1/0.824 or 0.56 pu loading on the base of the original system. A second approximation of the transformer reactance is indicated and this results in an increase loading to 0.58 pu on the original system base. From this it may be concluded that it is possible to more than double the loading on that part of the system which made up 0.6 of the original impedance by increasing the load power

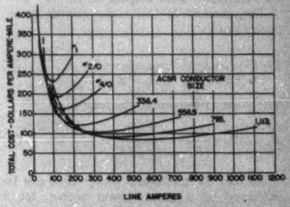

Fig. 9. Transmission costs in dollars per ampere-mile for seven steel-reinforced aluminum-cable conductors versus line loading in amperes. Fixed costs of $10,000 per mile, conductor cost, $0.50 per pound, and losses are evaluated at $300 per kilowatt

factor from 0.98 lag to 0.98 lead. In our example this corresponds to doubling the loading on all the lines.

We would like to refer to some unpublished work covering the economics of transmission line conductor size to indicate the possible economics that might be realized if the system is built to take this increased loading. Total cost has been determined on an ampere-mile basis as the function of three costs:

1. Those costs that are independent of conductor size such as right-of-way; terminal equipment; that part of the structure and insulation costs independent of conductor size; overhead ground wires and structure grounds, if required; and engineering.
2. Those costs that are a function of conductor size such as delivered cost of conductor; stringing costs; and that part of the structure and insulation costs which is a function of conductor size.
3. The cost of the power losses. This is a function of line loading and conductor size and is equal to $3\,I^2R$.

Fig. 9 shows some of the results of this study. It indicates that large conductors and heavy line loadings make for minimum line costs and it appears to justify the careful investigation of those factors affecting line loading.

Design of the Adjustable Lin-O-Phase Filter

REUBEN LEE
MEMBER AIEE

ALONG with the growth of power line carrier communications and consequent crowding of the frequency spectrum between 40 and 200 kc, the need for band-pass filters has arisen to prevent adjacent channel interference. With frequency-modulated transmission, requirements for these filters are unusually difficult, as can be seen from the response limits shown in Fig. 1. A specified maximum insertion loss of 17 decibels (db), a passband of ±3 kc, together with attenuation at ±8 kc of −100 db compared to mid-band present a technical problem unusual in two respects: Design of the filter to meet specified requirements, and measurement of the filter characteristics. In both the design and the measurements, special precautions are necessary prevent stray pickup from spoiling performance.

Electrical Design of Filter

Performance required of these filters is as follows:

1. Must adjust to any frequency from 40 to 200 kc.
2. Maximum mid-band insertion loss must not exceed 9 db at 40 kc and 17 db at 200 kc. Must be proportional at other frequencies.
3. Attenuation at frequencies must be ±8 kc from mid-band, 100 db minimum below mid-band loss.
4. Response at frequencies ±3 kc from mid-band must be within 5 db.
5. Maximum distortion must be 10 per cent (with 1,000-cycle audio and modulation index = 2.5) when tested in frequency-modulated transmitter-receiver setup.
6. Response and distortion limits must not be exceeded over a range of temperature from −20 degree centigrade (C) to +70 C, and humidities up to 95 per cent.
7. From 2 to 10 filters shall be capable of being connected in parallel across 100- to 200-ohm transmission line without interaction.
8. Absorption of local transmitter power, at any frequency, must be less than 1 per cent per filter.
9. Must be mechanically sturdy.

To prevent distortion to a frequency-modulated signal, it is necessary to consider both amplitude and phase response over the frequency range of each filter. An ideal filter would have attenuation and phase shift as shown in Fig. 2, i.e., the attenuation would be zero in the passband and infinite at all other frequencies. The phase shift would be linear throughout the passband. Then the signal at the filter output would be an exact replica of the input signal but delayed in time. Such a filter cannot be realized in practice because of inevitable coil and reflection losses.

Several types of filter have the necessary attenuation; shunt-turned band-pass configuration of Fig. 3 was chosen because of its simplicity and fairly linear phase shift over the pass band.[1] Linearity of phase shift in the Lin-O-Phase filter is sufficient to prevent distortion of frequency-modulated signals transmitted through the filter. This is indicated by the typical 100-kc carrier-frequency phase-shift curve shown in Fig. 4. Component values of inductance and capacitance are calculated from the usual design formulas which are given in the following.

For a full section, each coil has

$$L_1 = \frac{(f_2 - f_1)}{4\pi f_1 f_2} R \text{ henrys} \tag{1}$$

Each series capacitor has

$$C_1 = \frac{f_1 + f_2}{4\pi f_1 f_2 R} \text{ farads} \tag{2}$$

Each shunt capacitor has

$$C_2 = \frac{f_1}{\pi f_2 (f_2 - f_1) R} \text{ farads} \tag{3}$$

where

f_1 = lower cutoff frequency
f_2 = upper cutoff frequency
R = filter characteristic impedance

Frequencies f_1 and f_2 lie somewhat outside of the passband. Calling the frequency spread for 3-db response BW

$$\frac{f_2 - f_1}{BW} = 1.4$$

To avoid distortion, phase shift must be close to linear from f_1 to f_2. For a 14-section filter with the response of Fig. 1 and phase shift of Fig. 4, distortion was 8 per cent maximum.

The wire used in winding the coils is Litz. Coil Q changes with frequency, as shown in Fig. 5. All coils are vacuum-impregnated in high-grade wax to exclude moisture and maintain Q under extreme humidity. The need for high Q is greatest at the highest carrier frequencies. At these frequencies, mid-band loss would exceed the limit if Q were lower than 180.

The filter is made adjustable so that it may be tuned to any frequency within the range. A total of 16 different designs covers the carrier band of 40 to 200 kc, with each filter covering about a 10-per-cent frequency range. These filters are all similar in construction and differ from each other only in the values of inductance and capacitance necessary to tune the filter to the desired frequency. Tuning is accomplished by an adjustable slug within each coil. The range over which

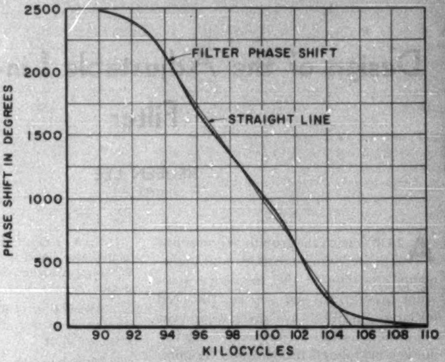

Fig. 4. Typical Lin-O-Phase filter phase shift versus frequency

the coil can be tuned is limited to 25 per cent of maximum inductance to maintain the coil Q values necessary to keep insertion loss within the desired limits.

To prevent loading of the power line with several parallel-connected filters, high filter impedance Z_0 is used, on the order of 10 to 20 kilohms. For the frequency range under consideration, a filter having Z_0 in the 10,000- to 20,000-ohm range gives convenient values of C and L. A high impedance filter operating between resistive terminations $R_1 = R_2 = Z_0$ prevents absorption of local transmitter power by the filter input sections. Filter impedance Z_0 varies with frequency, as shown in Fig. 6. The mid-shunt impedance drops to low values at frequencies below f_1 and above f_2. A transmitter operating at these frequencies would deliver most of its power into the filter if it were not for the high value of Z_0.

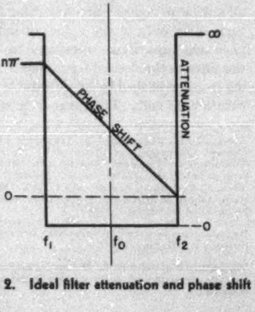

Fig. 2. Ideal filter attenuation and phase shift

Physical Design of Filter

Fig. 7 shows the Lin-O-Phase filter with the cover off and with a section of the filter shown separately. Each section is mounted on micarta angle as a separate subassembly. A core surrounding the adjustable coil has two half-cups of powdered iron cemented together. On the top half is a brass turret which supports the tuning slug. Both cups and slug are molded of finely divided iron particles and an insulating bond. Core temperature coefficient of permeability is 0.002 per cent per C. At the sides of the coil are mounted the series and shunt capacitors. Wiring between sections passes through notches in the partition. Components are not grounded to the case, but the return wire, G in Fig. 3, is insulated to eliminate ground currents which might link directly between terminals without passing through the filter.

Each filter section is completely shielded from each other section. Shielding is necessary because of stray flux from the adjustable coils. Such shielding is not necessary in fixed-frequency filters using toroidal coils; with care in manufacture, toroidal stray flux can be made negligible. The filter case itself is made of cast iron and has 15 compartments, one for each section. The first and last sections are half-sections for matching purposes. Each compartment is lined with a nonferrous metallic liner to maintain coil Q at a high value. If the nonferrous liner were omitted, stray flux from the coil would cause sufficient loss in the cast-iron case to degrade Q below an acceptable value.

The assembly is mechanically quite rugged. Of the many filters which have been shipped so far, all have withstood shipping shocks with no change in tuning or other damage.

Stray magnetic flux emanating from the top of the core in each compartment is shown approximately by the thin lines in Fig. 8. In this figure, the nonferrous liner is aluminum. Most of the flux crosses directly from the plunger to the cup core, as indicated by the short horizontal lines. Small inevitable air gaps exist around the plunger and where the cup cores are cemented together. Some of the flux from the plunger gap re-enters the cup core at some distance from the

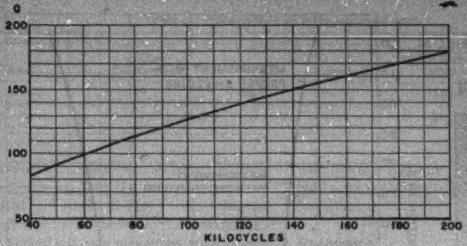

Fig. 5. Variation of filter coil Q with frequency

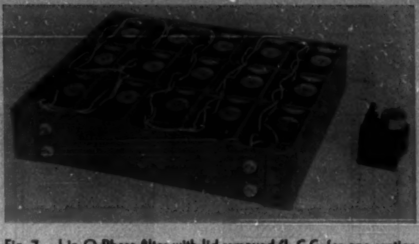

Fig. 7. Lin-O-Phase filter with lid removed ($L_1C_1C_1$ for one section shown separately)

plunger. Other flux lines strike the thick top wall of the turret and cause eddy currents to be set up in the direction shown by the arrow points and tails. These eddy currents cause most of the flux to be deflected away from the turret so that very little enters the turret except for a few mils of depth on the inner surface. The flux is further deflected away from the sides of the turret by eddy currents shown along the vertical walls and re-enters the core at the base of the turret. A few of the flux lines leak out of the small gap between the turret and the cup core where they fan out until they strike the aluminum liner. Here, again, they set up eddy currents which deflect them down toward the gap between the cup cores. A much smaller amount of flux penetrates the aluminum liner. This is represented by the single line which sets up eddy currents in the cast-iron partition wall, and which in turn deflects flux back to the iron core.

Field strength H, shown as an ordinate and causing this stray flux, is indicated qualitatively at the top of Fig. 8 with abscissa corresponding to radial distance from the center of the plunger. The turret shields the current at the top of the coil so effectively that it is not necessary to use an iron cover for the filter. The cover used with the filter of Fig. 7 is made of 1/8-inch thick aluminum.

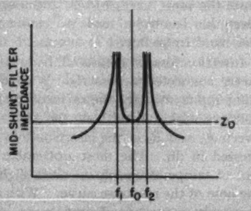

Fig. 6. Variation of filter impedance with frequency

In each compartment, stray flux strikes the nonferrous liner and sets up shielding eddy currents in a similar manner. Only a very small fraction of the total stray flux reaches the cast-iron partitions between compartments. What little flux does reach the cast iron penetrates the casting walls to a still smaller surface skin than in the nonferrous liner. Attenuation of the stray magnetizing force produced by each coil is thus effected in two stages: first, by the liner and, second, by the case. The strength of the magnetizing force at any distance x from the surface varies accordingly to the following equation

$$H=H_0\epsilon^{-\frac{x}{\delta}} \tag{4}$$

where

H_0 = magnetizing force at the surface
$\delta = 1{,}980\sqrt{\rho/\mu f}$, inches
ρ = resistivity, ohm-centimeters
μ = permeability
f = frequency, cycles

In this equation, δ is known as the depth of penetration; it is the distance from the surface at which eddy-current density is 36.8 per cent of the surface-current density. For any nonferrous metal, μ is unity and, for cast iron, it is approximately 1,000. The depth of penetration for aluminum at 100 kc is approximately 0.01 inch and for cast iron it is 0.0017 inch. Thus the pickup in the wiring from section to section is reduced to a very small amount by cast-iron walls of 1/8-inch thickness and liners 0.025-inch thick. Using the foregoing equation, the attenuation caused by copper alone is as follows

$$H=H_0\epsilon^{-0.025/0.00817}=0.045H_0 \text{ for 0.025-inch thickness}$$

$$H=H_0\epsilon^{-0.125/0.00817}=0.25\times10^{-6}H_0 \text{ for 0.125-inch thickness}$$

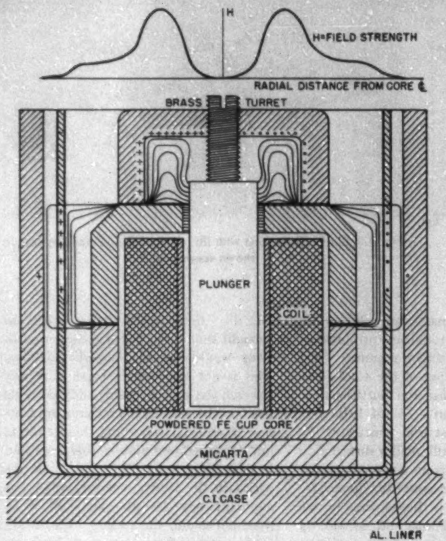
The shielding effect of thick walls is quite apparent. For the 1/8-inch wall, the magnetic field strength is attenuated 132 db. Because of this, it might be thought that 1/8-inch thick copper partitions would provide enough shielding. This is not sufficient because, part way through the wall, opposing eddy currents from neighboring compartments are flowing. Resultant stray flux thus tends to link other sections and by-pass the filter. Besides, this stray flux could link the wiring in the carrier receiver, which has approximately 100-db gain. At 8 kc from mid-band, the pickup with an all-copper case is large enough to limit attenuation to about 70 db and throw the filter response out of limits.

Hence, dual shielding is required: iron to attenuate stray flux, and nonferrous metal to keep most of the stray flux out of the iron and, hence, keep coil Q high. The attenuation of magnetizing force for various thicknesses of cast iron, copper, and aluminum, is given in Table I.

The tremendous calculated attenuation of 609 db with 1/8-inch thick iron walls is, of course, more than needed; but in a casting, 1/8-inch thick walls are the minimum practicable. A fabricated steel case of thinner stock would also be amply effective. In Table II are figures showing the effect on Q of a 200-kc coil with and without nonferrous liners.

Measurements

To measure the performance of a filter which meets the requirements of Fig. 1, it is necessary to observe several unusual precautions. To get accurate readings, the residual or stray voltages should be at least 20 to 30 db below the minimum expected filter output or, for this case, about 120 to 130 db or more below mid-band. Therefore, noise filters must be used in all power lines entering the measuring booth to exclude radio-frequency pickup from these lines. Not only must the booth be shielded but there must be a shield between the input and output terminals of the filter. The main reason



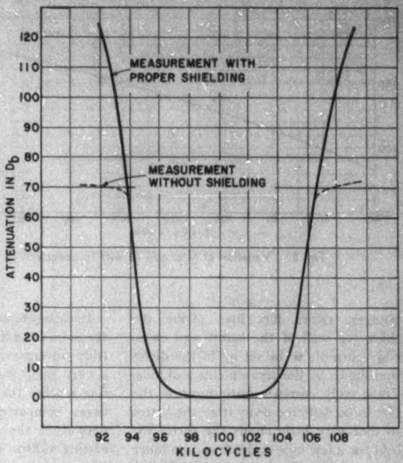


Fig. 8 (left). Approximate field strength and flux distribution in filter compartment

Fig. 10 (above). Effect of shielding on filter response measurements

for this second set of shields is to prevent the output voltmeter from picking up stray flux from the signal generator directly through the air. Fig. 9 shows the shielding which was used in making measurements on this filter. Without such shielding or with the filter cover removed, the attenuation curve apparently flattens off at about 70 db, as shown dotted in Fig. 10. Without the cast-iron case, there is sufficient pickup of stray flux from the input end sections of the filter by the voltmeter power leads to indicate even less attenuation.

Signal generator output should be a distortion-free sine wave. The signal generator power supply should be well filtered to eliminate hum. Beat frequencies caused by harmonics or hum are effectively detected by the skirts of the response curve, so that using poor input wave form may result in erroneous filter output.

Attenuation is measured conveniently on an electronic voltmeter with 11 ranges from 0.001 to 100 volts full scale. This type of meter has an electronic amplifier, the gain of which is adjusted for each range. Consistency of readings is checked by taking output at some readable point on two different scales. Starting with mid-band attenuation and proceeding to 8-kc below mid-band, it is possible to check every range in this manner. Unless such a check is made, nonlinearities in the voltmeter amplifier may cause inaccurate measurements.

Alignment of a filter of this type may be conveniently done by using an oscilloscope to indicate resonance of the shunt arms of each section with the following section short-circuited. Voltage minima and maxima occur with proper tuning of the respective alternate sections. In effect, this method means that L_1 and C_2 of each section, Fig. 3, are tuned to the upper cutoff frequency. When the following section is short-circuited, the series capacitor C_1 changes this tuning so that the filter is tuned as a complete unit to mid-band frequency $f_0 = \sqrt{f_1 f_2}$. This is not quite the same as $(f_1 + f_2)/2$, and a small correction has to be made to center the mid-band frequency.

Insertion loss is measured by a voltmeter connected across R_2. With constant input voltage, the ratio of output voltages with and without the filter between R_1 and R_2 is the insertion loss expressed in db. The most noticeable effect of temperature was to shift slightly the nose of the response curve. With the low temperature coefficient cores, this shift was approximately ±250 cycles as the temperature was changed from −20

Fig. 9. Shielding used for attenuation measurements

Table I. Attenuation of Magnetizing Force

Metal	ρ, Ohm-Centimeters	μ	δ, Inch	Db Attenuation of H By 0.025-Inch Thick	Db Attenuation of H By 1/8-Inch Thick
Cast iron	80	1,000	0.00177	122	609
Copper	1.7	1	0.00817	27	132
Aluminum	2.7	1	0.0103	21	106

Table II. Effective Q of a 200-Kc Coil

Filter Compartment, Thickness	Coil Q
1/8-inch copper	195
1/8-inch iron	76
1/32-inch iron	76
1/8-inch iron+1/32-inch copper liner	193
1/32-inch iron+1/32-inch copper liner	194

to +70 C. There was sufficient latitude in design so that the response remained within the limits of Fig. 1 when temperature was varied between these extremes.

Distortion was measured with a conventional distortion meter connected in the frequency-modulated receiver audio output. Although distortion was somewhat different at different carrier frequencies, the largest variations occurred with temperature changes. From −20 to +70 C, the distortion varied between 5 and 8 per cent at a given frequency.

Conclusion

In conclusion, it may be said that tunable frequency-modulated receiver filters with ±3-kc bandwidth and 100-db attenuation of unwanted signals are entirely practical for power line carrier frequencies with careful design. Particularly necessary is the provision of ferrous partitions between filter sections to prevent stray coupling which would otherwise by-pass the filter; nonferrous shielding is not sufficient in itself for such performance.

Discussion

R. W. Beckwith (General Electric Company, Syracuse, N. Y.): The author is to be complimented on this well-written and very informative paper. At first the title suggested that each filter might be adjustable over the entire carrier spectrum of 40 to 200 kc; however, it is realized that this approach is not practical and the division of the spectrum by 16 is a good compromise.

I should like to ask the academic question of whether the author believes the ideal characteristics of Fig. 2 would permit distortion-free reception of a frequency-modulated signal or whether the loss of higher order side bands would still produce distortion.

My company has found that 100 db can also be obtained by multiple thickness nonmagnetic shielding; however, the method described in the paper is certainly one good way of achieving the desired result.

Reuben Lee: Mr. Beckwith's question on the loss of higher order side bands is, as he points out, academic, because we achieved reasonable distortion reception with the actual filter. We do know, however, that linearity of phase shift has greater influence on distortion than attenuation just outside the passband. There is no doubt that the loss of higher order side bands would cause some distortion, but the amount is negligible in comparison with that due to nonlinear phase shift.

It is interesting to note that Mr. Beckwith obtained 100 db by multiple thickness nonmagnetic shielding. Our calculations and tests indicate that these multiple shields would have to be very thick to produce the results described in the paper. This would add to the filter weight and size.

An Improved Approximate Technique for Calculating Cable Temperature Transients

F. C. VAN WORMER
ASSOCIATE MEMBER AIEE

IN THE cross section of the single conductor cable illustrated in Fig. 1, the thermal resistance, thermal capacity, and temperature of the insulation are not linear functions of the thickness of the insulation. Consequently, the rigorous solution[1] of the cable temperature transient problem is quite complicated and involves lengthy and time-consuming calculations.

An Approximate Solution

An approximate solution is obtained by lumping the constants of the cable and forming an equivalent π circuit, as shown in Fig. 2. In line with the practice followed in transmission line problems, half of the thermal capacity of the insulation may be placed with the thermal capacity of the conductor at conductor temperature and the other half may be placed with the thermal capacity of the sheath at sheath temperature.

This method of lumping half of the thermal capacity of the insulation at each side of the thermal resistance of the insulation as shown in Fig. 2 has been used by Buller.[2] Since the temperature gradient through the insulation is not a linear function of the insulation thickness, this method of allocating the thermal capacity of the insulation does not accurately represent the total heat stored in the insulation.

Nomenclature

T_a = air ambient temperature, C
Q_1 = thermal capacity of conductor including oil plus part of the thermal capacity of the insulation, watt-minutes per C per foot of cable
Q_2 = part of the thermal capacity of the insulation, watt-minutes per C per foot of cable
Q_3 = thermal capacity of cable sheath plus part of thermal capacity of the insulation, watt-minutes per C per foot of cable
P = that part of the thermal capacity of the insulation to be allocated at an inner isothermal
V_i = cross-section area of insulation, square inches
q_i = insulation thermal capacity, watt-minutes per C per square inch of insulation per foot of cable
Q_i = total thermal capacity of the insulation watt-minutes per C per foot of cable
t = time, minutes
ϵ = base Napierian logarithms
P_i = insulation thermal resistivity, C centimeters per watt
$K = 0.00522 P_i$
W = watts per foot of cable at conductor

An Improved Approximate Solution

MODIFIED EQUIVALENT π CIRCUIT

The accuracy of the approximate solution using lumped constant may be improved by allocating the thermal capacity of the insulation at conductor temperature and sheath temperature so that the total heat stored in the insulation is represented.

If P represents the part of the insulation thermal capacity to be placed at conductor temperature and $(1-P)$ the part to be placed at sheath temperature, the total heat stored in the insulation may be accounted for as follows

$$PV_iq_iT_c+(1-P)V_iq_iT_s=q_i\int_r^R T_x dA \qquad (1)$$

From Fig.1

$$dA=2\pi x dx \qquad (2)$$

$$V_i=\pi(R^2-r^2) \qquad (3)$$

The temperature distribution throughout the insulation is such that

$$T_c-T_x=WK\log_\epsilon\frac{x}{r} \qquad (4)$$

and

$$T_c-T_s=WK\log_\epsilon\frac{R}{r} \qquad (5)$$

Combining equations 1, 2, and 4 results in

$$PV_iq_i(T_c-T_s)+V_iq_iT_s=2\pi q_i\times \int_r^R\left(T_c-WK\log_\epsilon\frac{x}{r}\right)xdx \qquad (6)$$

After performing the indicated operations

$$PV_iq_i(T_c-T_s)+V_iq_iT_s =2\pi q_i\left[\frac{T_c(R^2-r^2)}{2}- WK\left(\frac{R^2}{2}\log_\epsilon\frac{R}{r}-\frac{R^2-r^2}{4}\right)\right] \qquad (7)$$

By combining equations 7, 3, and 5, after simplifying, yields

$$P=\frac{1}{2\log\frac{R}{r}}-\frac{1}{\frac{R^2}{r^2}-1} \qquad (8)$$

Values of P as a function of R/r are shown in Fig. 3.

It is interesting to note that when R/r is 1.0, the value of P from equation 8 is 0.50. This condition is equivalent to an insulated cylinder of infinite radius or a plane. For this case the temperature distribution is known to be a linear function of the insulation thickness, and placing half of the thermal capacity at each terminal temperature accurate accounts for the total heat storage.

Also R/r is 1.0 when $R=r$, which corresponds to zero thickness of insulation but, in this case, the thermal capacity of the insulation is zero.

MODIFIED EQUIVALENT *T* CIRCUIT

For small conductors with a heavy wall of insulation, further accuracy is obtained by the use of a modified equivalent T circuit, as shown in Fig. 4. In this case the thermal capacity of the insulation is placed part at the conductor, part halfway through the insulation thermal resistance, and part at the sheath. Since the insulation thermal resistance between r and x in Fig. 1 is proportional to log x/r, R_i is divided in half when

$$x/r=R/x \text{ or } x=\sqrt{Rr} \qquad (9)$$

The area of the insulation between r and x is

$$V_i'=\pi(x^2-r^2) \qquad (10)$$

The area of the insulation between x and R is

$$V_i''=\pi(R^2-x^2) \qquad (11)$$

Since $x/r=R/x$, the value of P as determined from equation 8 or Fig. 3 is the same for both parts of the insulation.

The thermal capacity of the insulation is then allocated as follows

At T_c place Pq_iV_i' (12)

at T_x place $(1-P)q_iV_i'+Pq_iV_i''$ (13)

at T_s place $(1-P)q_iV_i''$ (14)

Example

The accuracy of the three approximate solutions discussed is illustrated by applying these methods to a single conductor cable in air and comparing the resulting temperature transient with the results obtained, using distributed constants in accordance with the rigorous solution given in reference 1. The cable selected for the comparison is a single-conductor 250,000-circular-mil 0.69-inch core 0.560-inch paper insulation 0.125-inch lead sheath oil-filled cable. The resulting temperature transients are shown in Fig. 5.

The solution using an equivalent π circuit, lumping the thermal capacity of the insulation 50 per cent at the conductor and 50 per cent at the sheath, gives a considerably lower temperature rise than the exact solution using distributed constants. The solution using an equivalent π circuit, lumping PQ_i at the conductor and $(1-P)Q_i$ at the sheath, gives a considerable improvement in accuracy but for this rather small conductor and heavy wall of insulation, there is still a considerable difference between this approximation and the solution using distributed constants.

The solution using the modified equivalent T circuit of Fig. 4, lumping the thermal capacity of the insulation at the conductor, sheath and at the halfway point through the insulation thermal resistance as described in the foregoing, gives a very close check with the solution using distributed constants. The method of solution using the equivalent π and T circuits of Figs. 2 and 4 and the expansion theorem is outlined in Appendixes I and II.

The four methods of calculation result in the following temperature rise equations which were plotted in Fig. 5.

Using distributed constants

$$(T_c-T_a)=4.48-3.89\epsilon^{-0.0145t}- 0.52\epsilon^{-0.1850t}-0.07\epsilon^{-0.5200t}$$

Using the modified equivalent T circuit

$$(T_c-T_a)=4.48-3.94\epsilon^{-0.01438t}- 0.45\epsilon^{-0.1296t}-0.09\epsilon^{-0.3123t}$$

Using the equivalent π circuit and

$(P)-(1-P)$ allocation of the insulation thermal capacity

$$(T_c-T_a)=4.48-4.127\epsilon^{-0.01449t}-0.353\epsilon^{-0.0637t}$$

Using the equivalent π circuit and 50–50 allocation of the insulation thermal capacity

$$(T_c-T_a)=4.48-4.275\epsilon^{-0.01341t}-0.205\epsilon^{-0.[illegible]t}$$

In the preceding example the following constants were used:

$r=0.49$ inch

$R=1.05$ inches

$P_i=600$ C centimeter per watt

$R_i=2.39$ thermal ohms, C per watt per foot of cable

$R_S=2.09$ thermal ohms, C per watt per foot of cable

$Q_{\text{oil}}=151.0$ watt-seconds per C per foot of cable

$Q_{\text{conductor}}=136.5$ watt-seconds per C per foot of cable

$Q_{\text{insulation}}=1{,}014.0$ watt-seconds per C per foot of cable

$Q_{\text{lead}}=255.0$ watt-seconds per C per foot of cable

Conclusions

For cables with large conductors and moderate walls of insulation or small conductors with thin walls of insulation, the approximate solution using the equivalent π circuit of Fig. 2 and placing PQ_i at the conductor and $(1-P)Q_i$ at the sheath, is quite accurate and is very much less laborious than the rigorous solution using distributed constants.

The process of lumping the cable thermal circuit to form a 2-part network often gives sufficient accuracy. This method has been used by several engineers.[2,3] The method of lumping the cable insulation thermal capacity described in this paper results in improved accuracy, as seen in Fig. 5, with no appreciable extra work.

For cables with small conductors and heavy walls of insulation, the approximate solution using the modified equivalent T circuit of Fig. 4 and allocating the insulation thermal capacity in accordance with equations 12, 13, and 14, is sufficiently accurate for most engineering work. The labor of solving the T circuit is somewhat greater than for the π circuit but is still greatly less than for the solution using distributed constants.

The solution of the cubic equation for the three roots of the equivalent T circuit in Appendix II is easily performed by a digital computer. There are also several long-hand methods[4–6] for the solving of cubic equations which are quite easy to apply.

As soon as the solution for the conductor temperature T_c is reached, the solution for the insulation temperature T_x and sheath temperature T_s is readily obtained, as shown in Appendixes I and II. The use of the equivalent T circuit giving an intermediate insulation temperature is particularly desirable if oil demands and oil pressure drops are to be calculated.

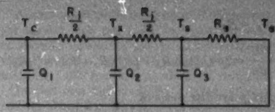

Fig. 4. Modified equivalent T electric circuit for the thermal circuit of cable in Fig. 1

Appendix I. Solution of the Equivalent π Circuit

Using the expansion theorem, the solution of the equivalent π circuit of Fig. 2 is as follows

$$T_c-T_a=W\left(R_i+R_S+\sum_p\frac{Y_p}{p\dfrac{dZ}{dp}}\epsilon^{-pt}\right)$$

$$T_s-T_a=W\left(R_S+\sum_p\frac{Y_p'}{p\dfrac{dZ}{dp}}\epsilon^{-pt}\right)$$

where

$$Y_p=pQ_sR_iR_S+R_i+R_S$$

Fig. 3 (below). Allocation of insulation thermal capacity

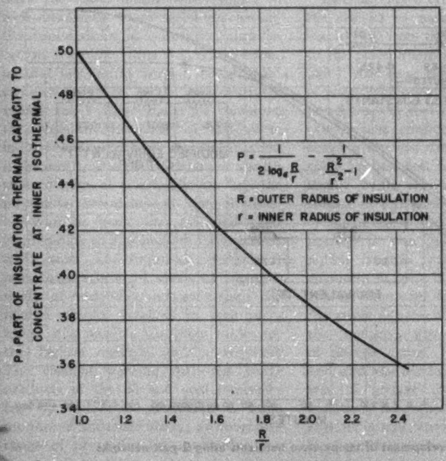

Fig. 5 (right). Calculated conductor temperature transients

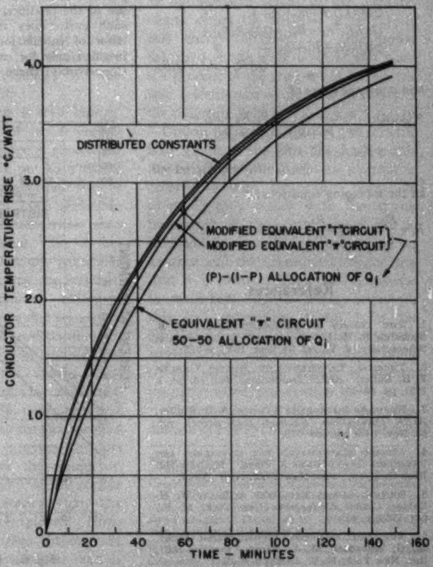

$$Y_p' = R_S$$

$$\frac{p\,dZ}{dp} = 2p^2Q_1Q_2R_IR_S + p[Q_1(R_I+R_S)+Q_2R_S]$$

and p are the roots of

$$p^2Q_1Q_2R_IR_S + p[Q_1(R_I+R_S)+Q_2R_S]+1=0$$

Appendix II. Solution of the Equivalent T Circuit

Using the expansion theorem, the solution of the equivalent T circuit of Fig. 4 is as follows

$$T_c - T_a = W\left(R_1+R_2+R_3+\sum_p \frac{Y_p}{p\frac{dZ}{dp}}\epsilon^{-pt}\right)$$

$$T_2 - T_a = W\left(R_2+R_3+\sum_p \frac{Y_p'}{p\frac{dZ}{dp}}\epsilon^{-pt}\right)$$

$$T_s - T_a = W\left(R_3+\sum_p \frac{Y_p''}{p\frac{dZ}{dp}}\epsilon^{-pt}\right)$$

where

$$Y_p = p^2Q_2Q_3R_1R_2R_3 + p[Q_2R_1(R_2+R_3) + Q_3R_3(R_1+R_2)] + R_1+R_2+R_3$$

$$Y_p' = pQ_3R_2R_3 + R_2 + R_3$$

$$Y_p'' = R_3$$

$$p\frac{dZ}{dp} = 3p^3Q_1Q_2Q_3R_1R_2R_3 + 2p^2[Q_1Q_2R_1(R_2+R_3) + Q_1Q_3R_3(R_1+R_2) + Q_2Q_3R_2R_3] + p[Q_1(R_1+R_2+R_3) + Q_2(R_2+R_3) + Q_3R_3]$$

and p are the roots of

$$p^3Q_1Q_2Q_3R_1R_2R_3 + p^2[Q_1Q_2R_1(R_2+R_3) + Q_1Q_3R_3(R_1+R_2) + Q_2Q_3R_2R_3] + p[Q_1(R_1+R_2+R_3) + Q_2(R_2+R_3) + Q_3R_3] + 1 = 0$$

In the foregoing equations:

$$R_1 = \frac{R_I}{2} \qquad R_2 = \frac{R_I}{2} \qquad R_3 = R_S$$

Discussion

F. H. Buller (General Electric Company, Schenectady, N. Y.): The author has presented a technique for the calculation of transients on underground cables which should give acceptable accuracy in most cases and which is actually very much simpler than the more rigorous technique involving distributed constants (see reference 1 of the paper). The equivalent π circuit with 50-50 allocation of the thermal capacity mentioned by the author has, in fact, been considered and rejected on the grounds of insufficient accuracy for the computation of thermal transients and oil demands of cables in free air or in underground ducts. If reasonable precision was desired in such cases, the method of distributed constants was used; and the author's simplification should be very welcome to engineers responsible for practical calculation in such cases.

In the case of a directly buried cable or pipe cable (see reference 2 of the paper) the over-all error involved in the use of the equivalent π circuit in question is very much reduced, since this circuit is a relatively small part of a rather large complex of thermal resistances and capacitances, which are necessary for the proper inclusion of the effect of the earth on the thermal transient. This is particularly true of oil-filled pipe cables, where a very considerable quantity of oil is involved; this oil follows quite closely the temperature changes of the pipe itself. However, even in such cases there is an advantage in using the author's equivalent π circuit, with (P) and $(1-P)$ allocation of the thermal capacity, since this can be done with practically no extra labor as compared with the use of 50-50 allocation. The use of the modified equivalent T circuit in such cases does materially increase the labor of calculation; and it is probably justified only for cables in air or in ducts. Conceivably, there may be some very exceptional problems where it might be justified for directly buried cables; but these problems would certainly be unusual ones.

An equivalent π circuit will not, in general, give the oil-demand curve its characteristic peak for cables in air or in ducts, although the maximum oil demand as calculated from an equivalent π circuit with (P) and $(1-P)$ allocation will approximate the maximum oil demand quite closely. Has the author found that the modified equivalent T circuit will, in general, give such a peak, and if so will this peak come at or close to the proper time?

J. H. Neher (Philadelphia Electric Company, Philadelphia, Pa.): The techniques for handling the distributed thermal capacitance of the insulation which the author has presented will be most useful to those of us who have been trying to develop procedures for calculating cable temperature transients which will be simple and still will have the accuracy required. In this connection, I should like to suggest a procedure using these techniques whereby the temperature transient may be readily calculated with almost any degree of accuracy.

As shown in Fig. 5, the modified equivalent T circuit is considerably more accurate than the modified equivalent π circuit during the initial portion of the transient. It will also be noted that during the latter portion of the transient the simpler π circuit has an accuracy comparable with the T circuit, which is sufficient for almost any application.

The objection to the T circuit, consisting as it does of a 3-part network, is of course that considerable labor is involved in formulating the corresponding 3-term exponential equation, and I doubt if any time will be saved by developing the temperature transient equation by this means instead of by the use of Bessel functions, as indicated in reference 1. The 2-term exponential equation for the π circuit or 2-part network, on the

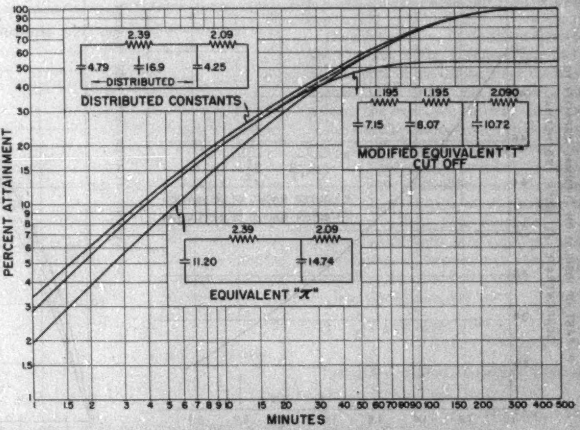

Fig. 6. Development of temperature transients using 2-part networks

other hand, is rather quickly determined, as shown in reference 3.

Considering the *T* circuit shown in Fig. 4, it will be apparent that during the initial part of the transient, its form is unaffected by the magnitude of Q_3 and R_3, since the heat flow will not have penetrated that far. Hence we may cut off the circuit at Q_3 and we have left a 2-part network which is readily solved. The resulting transient is shown in Fig. 6 of this discussion which also shows the transients calculated by the author using distributed constants and for the modified equivalent π circuit. Obviously, the cut-off network solution will not be correct during the latter part of the transient but during the initial part it will be seen to be considerably more accurate than the π circuit. It is a simple matter to develop a smooth envelope of these two curves, as shown by the dashed line, to obtain an over-all transient curve of reasonable accuracy.

Even greater accuracy during the initial portion may be obtained by suitably dividing the thermal capacitance of the insulation into three or four parts instead of two, but otherwise following the procedure as set forth by the author. This will result in a 4- or 5-part network of which only the first two sections are used, and will give increasingly greater accuracy where it may be required if the procedure is used for oil flow and pressure calculations.

The author is to be congratulated for having made a significant contribution in this respect.

F. C. Van Wormer: Mr. Buller asks if the use of the modified equivalent *T* circuit will give the oil-demand curve its characteristic peak.

The modified *T* circuit approach was applied to the example shown in Fig. 5 of an article by Shanklin and Buller in 1931[1]. The characteristic peak on the oil-demand curve and pressure drop curve was obtained.

An oil-demand peak of 62.5×10^{-6} cubic inches per second per foot was obtained at time of about 7.5 minutes. This compares with Fig. 5 of 63.8×10^{-6} cubic inches per second per foot at about 8 minutes.

A maximum pressure drop of 0.56 pounds per square inch per 1,000 feet was obtained in about 25 minutes' times. This compares with Fig. 5 of about 0.575 pounds per square inch per 1,000 feet also at about 25 minutes.

In this case the modified *T* solution gave results about 2 or $2^{1}/_{2}$% lower than the long rigorous solution. This is probably as close as some of the other data are known.

Mr. Neher's treatment of the modified *T* equivalent circuit is very intriguing and greatly reduces the labor involved in obtaining the cable temperature transient. I agree with Mr. Buller's statement that, "an equivalent π circuit or 2-part network will not, in general, give the oil demand curve its characteristic peak for cables in air or in ducts." I find that the location of the three roots by the method of reference 4 saves considerable time over the rigorous method involving Bessel functions. I wish to thank the discussers for their interest.

The Co-ordination of Power and Communication Cable Characteristics

H. D. SHORT
MEMBER AIEE

FROM the very beginning of the science of electricity, sometime in the first half of the 19th century, the need for insulated conductors has kept apace of scientific developments. In the early days the cable maker was obliged to seek insulating materials from among the commodities of commerce, such as cotton and silk yarns, paper, bitumen, natural oils, gutta percha, amber, and eventually rubber. Until comparatively recent times these materials remained the standard insulants of the cable industry. Today, however, the situation is drastically changed. From our wealth of knowledge of atomic physics, and the physicists' researches in the electrical behavior of gases and oils and their combination in agglomerate formulations with paper, and improved methods of manufacture brought about by constant study of processing methods (and the related physics involved in such processes), it is possible to design cables for the highest voltages so far required. The chemist working with the waste products of the oil and coal industries has succeeded in producing a large number of materials having an enormous range of properties and possessing the prime requisites of a good insulant, some of which permit the design of cables capable of efficient operation at the very high frequencies demanded by the progress of modern living.

Electric cables are, as is well known, the arteries by means of which energy is conveyed from the source of generation to the place where it is put to a useful task. And since the present-day society is essentially one based upon economic principles, the cost of transmission is an ever-present consideration. So it becomes a *sine qua non* that any particular cable be designed to carry the required energy with the maximum efficiency consistent with these economic principles.

In the early days of electrical engineering it was held—and indeed the notion is still prevalent among some engineers in spite of the vast accumulation of knowledge to the contrary—that the prime purpose of the insulant around the conductor was to prevent the loss of electric charge from the conductor, and that the conductivity of the copper was of greater importance than the quality of the insulant employed. However, it is now known that the insulant is of much greater importance; and it may be accepted that the chief role of the insulant is not so much to form a barrier to the loss of charge as to present a medium by means of which the transfer of energy along the conductor may be efficiently effected. The conductor acts more especially as a source of free electrons as well as guides the direction of energy flow; the flow takes place because of the physical action of the displacements within the medium. The rate of this energy transfer, i.e., the power delivered or the work done in unit time, is a product of the gradient of the electric field (electric stress) and the intensity of the magnetic field.

Under the subjection of the electric field gradient the free electrons within the conductor are forced to migrate in accordance with established laws. In so doing they collide with the atomic framework of the metal giving rise to heat energy, which is observed as resistance and the subsequent copper loss. And it is of more than passing interest to recall here that the energy supplying this loss enters the metal from the insulant around it, which is under the strain of the electric field—conforming to the equipartition theory of electromagnetic wave propagation.

All the schemes available for the transmission of energy, whether by mechanical

Y., January 31–February 4, 1955. Manuscript submitted December 29, 1953; made available for printing December 8, 1954.

H. D. SHORT is with the Canada Wire and Cable Company, Toronto, Ontario, Canada.

or electrical means, have one outstanding, common aim: the production of strain at the source of supply and its relaxation at the other end where the energy is expended. That is to say, there must occur a change from potential energy to kinetic energy, or the converse, in order for energy of any kind to be conveyed from one place to another. In the hydraulic system, pressure is developed; in the mechanical system it is the strain in the rotating shaft. Similarly, in the case of electric energy, transmission strain within the insulation is produced.

In nearly all engineering practice the energy used comes from the kinetic energy developed by a falling mass of water, or is derived from the conversion of the inherent potential energy existing between the atoms of oxygen and carbon into the kinetic energy of steam, such as takes place when water is heated by burning coal or any other organic substance. At the sending end of an electric transmission system the generators and transformers raise the potential energy of the electric field (or the strain) between the conductors to the highest possible level without occasioning too high losses or breaking down of the insulation. At the delivery end energy is expended by a relaxation of electric field forces.

Thus there occurs within the insulant a heat loss produced by the strain of the electric field which has become known as the dielectric loss. It is always necessary when dealing with high voltages or high frequencies to make sure that the proper insulating medium is chosen, and that the dielectric loss is not allowed to become so great as to cause thermal or electrical instability with eventual breakdown of the insulation sustaining the system.

The first part of the paper is restricted to a general consideration of the transmission of energy along a cable line without regard to any frequency limitation. The paper diverges in two directions, one having to do with low frequencies and high voltages and the other with high frequencies and low voltages. As one proceeds along these two lines of thought, the similarities and the disparities indigenous to the transmission of power on the one hand and intelligence on the other come more and more into common focus.

The paper is confined to the limiting case of what are known as coaxial cables, which for all intents and purposes means very much what the name implies, i.e., a cable whose conducting elements are in the form of circles having coincident lateral axes—a geometrically symmetrical system possessing the minimum electrostatic capacity and the maximum potential energy $(g^2)/(2C)$ relative to any other formation of one circle enclosed by another, and exhibiting unstable equilibrium in respect of the inner conductor which will permit it to move in any direction unless otherwise constrained.

Fig. 1 depicts the geometry of this type of cable: it is a coaxial cable in the simplest sense of having only two conductors. Quite obviously, of course, a coaxial cable could be constructed with any given number of conductors. However, from practical considerations the 2-conductor cable is of most interest and is the only one with which this paper is concerned. Although Fig. 1 shows the inner conductor to be in the shape of an annulus conforming to that of the outer conductor, it may be of a solid or cylindrical shape without upsetting the underlying physical principles involved, and very often occasions demand that it be of such a cross-sectional configuration.

Nomenclature

R = resistance per wire unit of length
L = inductance per wire unit of length
C = capacitance per wire unit of length
g = leakage per wire unit of length
Z = impedance per wire unit of length
Y = admittance per wire unit of length
Z_0 = characteristic impedance
ρ = propagation constant
α = attenuation constant, hyperbolic radians or nepers per wire unit of length
β = wave-length constant, radians per wire unit of length
f = frequency, cycles per second
λ = wave length, units of length
V = wave velocity along the cable, units of length per second
W = load impedance
E_a = design impulse voltage breakdown to neutral for the cable, kilovolts
k = dielectric constant
$\cos\theta$ = load power factor
P_n = natural load of the line
p = power transmitted at any point distance x from sending end
P_S = power input at sending end
g_c = electric stress at surface of the conductor in a cable, kilovolts per centimeter

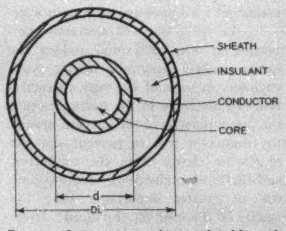

Fig. 1. Cross section of coaxial cable with annular conductor

General Consideration of the Transmission of Waves Along Cables

The fundamental parameters of the propagation of electromagnetic waves along a cable regardless of frequency are R, L, C, and g. In any infinite line, or finite line of practical linear dimensions, these parameters are reiterante and may be thought of as uniformly distributed along the cable circuit.

A combination of these parameters may be established to give two well-known complex quantities, named by Oliver Heaviside Z and Y. These complex quantities may be further dealt with by a process of mathematical deduction in accordance with the Lagrange classical method of arriving at the wave-transmission equation, and as first elucidated by Heaviside.

Thus certain additional quantities are obtained germane to all problems of a-c transmission in cables, whether the commodity transported is power in bulk to do useful work or intelligence to inform. They are

$$Z_0=\sqrt{Z/Y}$$

$\rho=\sqrt{ZY}$ hyperbolic radians per wire unit of length

two extremely important relationships, for they reveal after very little reasoning the essential characteristics which not only distinguish the two modes of transmission (low frequency and high voltage and the converse) but remain to identify and bring into prominence the respective design features which have to be considered. For, as Faraday once emphasized in discussing the velocity of electromagnetic propagation along wires or cables of different lengths, it is necessary to take into account the circumstances of the wires "being twined round a frame in a small space, or spread through the air through a large space or adhering to walls, or lying on the ground." It will be of interest to see how this state of affairs comes about. The propagation constant may now be written in the Cartesian co-ordinate or polar form best suiting our purpose: i.e.

$$\begin{aligned}\rho&=\sqrt{ZY}\\&=\alpha+j\beta=Ae^{j\theta}\end{aligned}$$

where two new terms, α and β, have been introduced. It is of more than

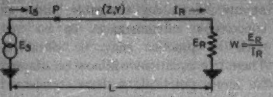

Fig. 2. Schematic diagram of steady-state transmission line

$e = E_S \cosh \rho x$

$i = I_S \cosh \rho x - \frac{E_S}{Z_0} \sinh \rho x$

where x is measured from the sending end

$e = E_R \cosh \rho x + Z_0 I_R \sinh \rho x$

$i = I_R \cosh \rho x + \frac{E_R}{Z_0} \sinh \rho x$

where x is measured from the receiving end

$(\cosh 0 = 1, \ \sinh 0 = 0)$

passing interest to note that the exponential function from which α as a transmission unit was derived was first revealed to unsuspecting electrical engineers in Montreal by the late Lord Rayleigh during the course of a lecture delivered in 1884.

The significance of Z_0, α, and β in respect to the propagation of electromagnetic energy along a cable will now be examined. Consider a single coaxial cable of length L transporting energy from the sending end to a load impedance W at the receiving end. This is shown in Fig. 2 merely to illustrate the juxtaposition of the complex quantities involved. The appropriate subscripts refer to the sending end and receiving end respectively.

The four familiar transmission equations of classical theory relating these quantities one to the other are given as a matter of reference. e and i are the voltage and current at any point P along the cable in terms of either the sending or receiving end components at a distance x from either end. Then at any point P at a distance x from the sending end

$$e = E_S \cosh \rho x - Z_0 I_S \sinh \rho x \tag{1}$$

$$= \left(\frac{E_S - Z_0 I_S}{2}\right)\epsilon^{\alpha x}\epsilon^{j\beta x} + \left(\frac{E_S + Z_0 I_S}{2}\right)\epsilon^{-\alpha x}\epsilon^{-j\beta x} \tag{2}$$

Similarly

$$i = I_S \cosh \rho x - \frac{E_S}{Z_0} \sinh \rho x \tag{3}$$

$$= \left(\frac{I_S - \frac{E_S}{Z_0}}{2}\right)\epsilon^{\alpha x}\epsilon^{j\beta x} + \left(\frac{I_S + \frac{E_S}{E_S}}{2}\right)\epsilon^{-\alpha x}\epsilon^{-j\beta x} \tag{4}$$

Hence it is at once evident that several things are happening to the wave as it proceeds along the cable. First of all, as long as W is finite, Z_0 tends to reduce the absolute value (as well as the complex value) of the voltage and alter that of the current at any point, and its complex value and the length of the line will determine to some extent the voltage regulation to be obtained in any particular case.

The second part of each equation, remembering that

$$\epsilon^{-j\beta x} = \cos \beta x - j \sin \beta x$$

shows that as the wave proceeds along the cable the absolute value (or magnitude) of both the current and the voltage at any point is decreased, in respect to the sending end conditions, according to the parameter α, i.e., attenuation is taking place. Also, the complex (or phasor) value of the current and voltage is being rotated with respect to the sending end through angles $= \beta$ radians. Fig. 3 illustrates these phenomena for the second part of each equation which involves a clockwise rotation because of $\epsilon^{-j\beta x}$. The result is a logarithmic spiral which, of course, will evolve into a circle as α is decreased. In other words, α expresses the change in the absolute value of the current or voltage, β the change of phase of the current or voltage, and Z_0 a definite reduction depending on its magnitude and hence on the cable design. However, it is not quite correct to infer that Z_0 alone is dependent on the cable design, for it is all too obvious that both α and β must also be functions of the initial design consideration. If f and λ are introduced and it is noticed that $\cos \beta x$ and $\sin \beta x$ are repeated each time βx passes through 360 degrees or 2π radians, it becomes evident that the angle between current or voltage at any point in the cable and the current or voltage at another point distance λ therefrom $= 2\pi$ radians.

Since these two points are 1 cycle apart it will take a wave $1/f$ seconds to travel the distance λ. The equation for velocity V is

$$\begin{aligned} V &= dx/dt \\ &= \lambda/(1/f) \\ &= \lambda f \\ &= 2\pi f/\beta \end{aligned}$$

As has already been stated, the transfer of energy along the cables takes place in the insulating medium, and it would be expected that the inbred properties of the medium would have some influence on the velocity of the waves. This has been clearly shown to be the case as evinced by the equation for velocity, viz. $(2\pi f)/\beta$, and it has been shown that β bears a definite relationship to two of the four initial parameters C and g, whose magnitudes are dependent upon the character of the insulating material and upon the frequency of transmission. From this point of view the wave velocity then becomes doubly dependent upon the frequency.

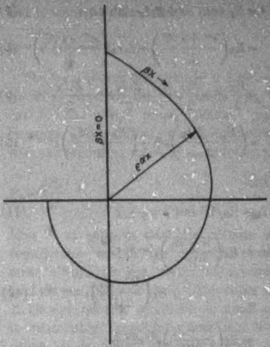

Fig. 3. Logarithmic spiral

In any chosen medium the wave velocity can never, so far as is known, exceed the speed of light: 300×10^6 meters per second. In cables the wave velocity is appreciably less, being a function, as may be readily discerned, of the dielectric constant of the medium whose influence becomes greater in these respects as the frequency is increased. Since

$$\rho = \sqrt{ZY} = \alpha + j\beta = \sqrt{(R + jL\omega)(g + jC\omega)}$$

then

$$\begin{aligned} \alpha^2 + 2j\alpha\beta - \beta^2 &= (R + jL\omega)(g + jC\omega) \\ &= Rg + j(Lg\omega + RC\omega) - \omega^2 LC \end{aligned}$$

The real and imaginary parts may be equated. Therefore

$$\begin{aligned} \alpha^2 - \beta^2 &= Rg - \omega^2 LC \\ 2\alpha\beta &= Lg\omega + RC\omega \end{aligned}$$

from which it may be shown that

$$\alpha = \left[\sqrt{\left(\frac{R^2 + \omega^2 L^2}{2}\right)\left(\frac{g^2 + \omega^2 C^2}{2}\right)} + \left(\frac{Rg - \omega^2 LC}{2}\right)\right]^{1/2} \tag{5}$$

$$\beta = \left[\sqrt{\left(\frac{R^2 + \omega^2 L^2}{2}\right)\left(\frac{g^2 + \omega^2 C^2}{2}\right)} - \left(\frac{Rg - \omega^2 LC}{2}\right)\right]^{1/2} \tag{6}$$

Referring to the other pair of transmission line equations, then taking a point P, this time at a distance x from the receiving end, we may write

$$e = E_R \cosh \rho x + Z_0 I_R \sinh \rho x \qquad (7)$$

$$= E_R\left(\frac{\epsilon^{\rho x} + \epsilon^{-\rho x}}{2}\right) + Z_0 I_R\left(\frac{\epsilon^{\rho x} - \epsilon^{-\rho x}}{2}\right) \qquad (8)$$

$$= \frac{E_R}{2}\epsilon^{\rho x} + \frac{E_R}{2}\epsilon^{-\rho x} + \frac{Z_0 I_R}{2}\epsilon^{\rho x} - \frac{Z_0 I_R}{2}\epsilon^{-\rho x} \qquad (9)$$

$$= \left(\frac{E_R + Z_0 I_R}{2}\right)\epsilon^{\rho x} + \left(\frac{E_R - Z_0 I_R}{2}\right)\epsilon^{-\rho x} \qquad (10)$$

but

$$I_R = E_R/W \text{ and } \rho = \alpha + j\beta \qquad (11)$$

$$e = E_R\left(\frac{W+Z_0}{2W}\right)\epsilon^{(\alpha+j\beta)x} + E_R\left(\frac{W-Z_0}{2W}\right)\epsilon^{-(\alpha+j\beta)x} \qquad (12)$$

$$= E_R\left(\frac{W+Z_0}{2W}\right)\epsilon^{\alpha x}\epsilon^{j\beta x} + E_R\left(\frac{W-Z_0}{2W}\right)\epsilon^{-\alpha x}\epsilon^{-j\beta x} \qquad (13)$$

Similarly

$$i = \left(\frac{I_R + \frac{E_R}{Z_0}}{2}\right)\epsilon^{\rho x} + \left(\frac{I_R - \frac{E_R}{Z_0}}{2}\right)\epsilon^{-\rho x} \qquad (14)$$

but

$$E_R = W I_R \text{ and } \rho = \alpha + j\beta \qquad (15)$$

therefore

$$i = I_R\left(\frac{1 + \frac{W}{Z_0}}{2}\right)\epsilon^{(\alpha+j\beta)x} + I_R\left(\frac{1 - \frac{W}{Z_0}}{2}\right)\epsilon^{-(\alpha+j\beta)x} \qquad (16)$$

$$= I_R\left(\frac{Z_0+W}{2Z_0}\right)\epsilon^{\alpha x}\epsilon^{j\beta x} + I_R\left(\frac{Z_0-W}{2Z_0}\right)\epsilon^{-\alpha x}\epsilon^{-j\beta x} \qquad (17)$$

Another variable has been introduced into the problem, namely load impedance W. Its significance will be more obvious later when considering practical matters in high-voltage transmission and high-frequency transmission.

Reference has been made to the copper loss in the conductors and the dielectric loss in the insulating medium, and the fact that thermal instability apart from the question of electric breakdown must not be allowed to exist. This, of course, is true of any class of cable, particularly so at high voltages because of the dielectric loss which increases as the square of the voltage, but only as the first power of the frequency.

The general equations which express the way in which the transmission line parameters enter into the physical state of affairs concerned with these losses are equation 7 and

$$i = I_R \cosh \rho x + \frac{E_R}{Z_0}\sinh \rho x \qquad (18)$$

The copper loss and the dielectric loss respectively at any point distance x from the receiving end are i^2R, in watts per wire unit of length, and ge^2, in watts per wire unit of length. Then

$$i^2R = \left(I_R \cosh \rho x + \frac{E_R}{Z_0}\sinh \rho x\right)^2 R \qquad (19)$$

$$= \left(I_R \cosh \rho x + \frac{W}{Z_0} I_R \sinh \rho x\right)^2 R \qquad (20)$$

$$= I_R^2 R\left(\cosh \rho x + \frac{W}{Z_0}\sinh \rho x\right)^2 \qquad (21)$$

$$ge^2 = (E_R \cosh \rho x + Z_0 I_R \sinh \rho x)^2 g \qquad (22)$$

$$= \left(E_R \cosh \rho x + \frac{Z_0}{W} E_R \sinh \rho x\right)^2 g \qquad (23)$$

$$= E_R^2 g\left(\cosh \rho x + \frac{Z_0}{W}\sinh \rho x\right)^2 \qquad (24)$$

If

RTH_0 = thermal resistance through which the copper loss flows

RTH_{0D} = thermal resistance through which the dielectric loss flows both in accordance with the established laws of thermal energy flow

T_R = temperature rise of the inner conductor above ambient

$$i^2 R RTH_0 + ge^2 RTH_{0D} = T_R \qquad (25)$$

since Ohm's law for steady heat flow states that the thermal resistance × watt loss = temperature rise, and hence

$$I_R^2 R\left(\cosh \rho x + \frac{W}{Z_0}\sinh \rho x\right)^2 RTH_0 + E_R^2 g\left(\cosh \rho x + \frac{Z_0}{W}\sinh \rho x\right)^2 RTH_{0D} = T_R \qquad (26)$$

The receiving end conditions are as follows:

When $W = Z_0$

$$(\cosh \rho x + W/Z_0 \sinh \rho x)^2 = (\cosh \rho x + \sinh \rho x)^2 = (\epsilon^{\rho x})^2 = \epsilon^{2\rho x}$$

hence

$$\epsilon^{2\rho x}(I_R^2 R RTH_0 + E_R^2 g RTH_{0D}) = T_R$$

When $W = \alpha$, $I_R = 0$, and $Z_0/W = 0$

$$\left(\frac{E_R^2 R}{Z_0^2}\sinh^2 \rho x\right)RTH_0 + (E_R^2 g \cosh^2 \rho x)RTH_{0D} = T_R$$

When $W = 0$ and $E_R = 0$

$$(I_R^2 R \cosh^2 \rho x)RTH_0 + (Z_0^2 I_R^2 \sinh^2 \rho x)RTH_{0D} = T_R$$

From equations 5, 6, 13, 17, and 26 the current rating under steady-state conditions, and the current and voltage at any point along the cable, under all conceivable circumstances to be met with in practice may be obtained. These five equations will now be adapted to more practical matters concerned with the initial objective of bringing into greater emphasis the similarities and disparities between high-voltage (h-v) transmission and high-frequency (h-f) transmission.

High Voltage and Low Frequency

The ordinary metallic-sheathed single-conductor power cable employed in the transporting of bulk energy represents a coaxial cable in which the inner conductor only forms part of the electric transmission circuit. Only under certain preconceived conditions does any current flow in the outer conductor, and it may normally be assumed to be at ground potential or approximately so. Spurious currents, caused by induction effects, may flow in the outer conductor, but they are not included in the power circuit transferring energy, although their effects thereon cannot always be ignored.

For successful performance in service over long periods of time, it is necessary to interpose between the two coaxial elements a suitable dielectric material. For h-v cables their material must be such that impunity from breakdown is reasonably assured, so the factors of safety relative to internal and atmospheric voltage surges must be properly chosen.

In the present state of knowledge this dielectric takes the form of a relatively solid, though not rigid, material thoughtfully designed and carefully processed in the hands of those familiar with high-voltage practices. In the case of cables to operate at high voltages it is of utmost importance that this should be so, and a reputable manufacturer long experienced in designing, making, and handling high-voltage cables is a vital factor in any project.

That is all that needs to be said here in regard to the design of h-v cables and their peculiar characteristics which distinguish them from other cables of the low-frequency class. However, it might be well to draw attention to a few other aspects of h-v cables as such.

First of all, with the original coaxial configuration in mind, it is apparent that the electrostatic capacity parameter of the transmission equations is an inverse logarithmic function of the two diameters. And for any two given diameters the symmetry of coaxial arrangement yields a minimum value of C and the maximum potential energy, which, of course, is a prime requisite of any h-v cable.

It also becomes noticeable that increasing the diameter of the outer or ground electrode further decreases C and increases the potential energy, but in so doing physical limitations and economical considerations must be taken into account. Thus the value of C and (concomittantly) the outer electrode diameter must be wisely chosen for any particular design.

From the point of view of the factors of safety in respect of internal or switching surges and atmospheric surges, C is of vital concern for it may be considered as the determinant in these matters. Nowadays there is considerable and well-deserved emphasis put upon the impulse strength of electric equipment. This is because of the need to maintain a predetermined impulse level throughout the transmission system and certain levels have been established by the various standardizing bodies. Hence the impulse voltage breakdown strength of any h-v cable is becoming the greater criterion of the dielectric design and insulant thickness, so that C is found limited to a value dictated by these circumstances, above and below which one cannot trespass. For any particular h-v rating and cable design (and conductor size) C is then, to all intents and purposes, a given quantity

$$C=\frac{1.11krgc}{2E_a} \text{ micromicrofarads per wire centimeter}$$

where r is the conductor radius.

The parameter R, or more explicitly the conductor size, for h-v cables is not usually dependent upon steady-stated current rating considerations; it is a function more especially of the voltage rating and cable design. Inductance L is largely determined in a 3-phase system by the center to center spacing of the three phases, and here again symmetry of the array is an important factor requiring attention. For all h-v cables of conductor sizes of the order of 500,000 circular mils and larger, a frequency of 60 cycles per second, and close spacing of the phases

$$\omega L=1.9R \text{ as a loose approximation}$$

Since the insulant must (for reasons not needing explanation) be of the highest grade, the value of g is about negligible in comparison with C, i.e., $g<<C$, so that for the attenuation constant an equation is found

$$\alpha=\sqrt{0.12\omega RC}$$

from which it may be noticed that the attenuation constant is to some degree related to the copper loss and the dielectric loss. Similarly, the wave-length constant may be found from the approximate equation

$$\beta=\sqrt{2.02\omega RC}$$

so that, given the load impedance W the voltage drop and regulation of any circuit may be computed from equations 7 and 13 or

$$e=E_R\cosh\rho x+\frac{Z_0}{W}E_R\sinh\rho x \tag{27}$$

These equations for α and β tell something very specific about a h-v transmission circuit transporting bulk energy, i.e., power transmission. α and β will have very low values comparatively speaking and since $\lambda=(2\pi)/\beta$ the wave length of the line is long. The long wave length gives rise to a predominant characteristic of any power cable, that of being extremely short in terms of the wave length. The small value of α means that the circuit is highly efficient in regard to the amount of power delivered compared to the input power. This is important because large amounts of power are involved, and a small drop in efficiency means an energy loss of some monetary value, the capitalized value of which could be of some consequence.

On comparatively long h-v circuits the angle between the sending end and receiving end voltages represented by β is of importance, as well as the characteristic impedance Z_0. It has, e.g., been shown that the voltage at the receiving end under open-circuited conditions could conceivably be the decisive limitation to successful operation of a long circuit. If the circuit is open at the receiving end, $W=\alpha$ and

$$E_S=E_R\cosh\rho L \tag{28}$$

From this it may be seen that at some frequency or frequencies and certain circuit lengths L it would be feasible for E_R to exceed E_S, the well-known Ferranti effect. By suitable manipulation it can be determined that as long as $\beta<1.78\alpha$ the Ferranti effect will not exist.

Now consider one other aspect of any h-v transmission line. At some particular value of I_R for a given E_R (voltage to neutral) the leading and lagging wattless components of the power received can be made equal. Then, in accordance with the equipartition theory

$$1/2CE_R^2=1/2LI_R^2$$

and

$$E_R/I_R=\sqrt{L/C}$$

and it transpires now that

$$Z_0=\sqrt{L/C}=W$$

The total power delivered in a 3-phase circuit is given by the expression $3E_RI_R\cos\theta$. At unity power factor, this becomes $3E_RI_R$, from which, together with the preceding value of Z_0, it follows

$$P_n=\frac{3E_R^2}{Z_0}$$

Now it so happens that for circuits of considerable length the absolute load must always be less than the natural load as just defined; hence the value of Z_0 should, on this score, be as small as is reasonably possible; and for h-v cables, it is about one-eighth that of overhead lines.

The relationship whereby the energy stored in the electric field is equated to the energy stored in the magnetic field will be recognized as representative of the conditions obtaining when oscillatory energy is present in a cable line, or when a lightning discharge suddenly impresses on the cable a quantity of energy which is propagated along the cable as a "pure" travelling wave or impulse; in either case R and g must be very small, relative to C and L, in so far as the manifestation of these phenomena are concerned. For oscillatory energy to persist for any finite time the losses must be relatively insignificant, i.e., Z_0 is again equal to $\sqrt{L/C}$, and it can be shown that

$$\alpha=1/2\frac{R}{Z_0}+1/2gZ_0 \tag{29}$$

$$\beta=\omega\sqrt{LC} \tag{30}$$

Now neglecting the internal inductance of the inner conductor and assuming once again the cables of a 3-phase circuit to be in close proximity, it becomes admissible within the bounds of reasonable accuracy to write

$$\sqrt{LC}=3.33\sqrt{k}\times10^{-11}$$

(where units of length are in centimeters). For overhead lines $k=1$ (the dielectric constant of dry air) in clement weather and

$$\sqrt{LC}=3.33\times10^{-11}$$

which means that the velocity of the pure wave is about that of light (300×10^6 meters per second) from the relationship

$$V=\frac{\omega}{\beta}=\frac{1}{\sqrt{LC}} \text{ centimeters per second}$$

For cables k has an upper limit of about 6; therefore an average value of $\sqrt{LC}$ would be

$$\sqrt{LC}=5.1\times 10^{-11}$$

For a h-v cable $k=3.6$ and

$$\sqrt{LC}=1.9\times 10^{-11}$$

giving a velocity for the pure travelling wave of some 99,000 miles per second.

It is now seen that in a h-v cable the energy wave of the lightning discharge travels at a much lower velocity than in an overhead line. In terms of the impulse level of the system and the conductor size

$$\sqrt{LC}=23.3\sqrt{\frac{kr}{E_a}}\times 10^{-10}$$

where r is the radius inner conductor in centimeters.

The small value of Z_0 for a h-v cable in comparison with that of an overhead circuit is of some significance when considering the effects on lightning discharges and oscillating energy phenomena. Under these circumstances equation 29 applies, the first term of which represents that part of the attenuation due to the copper loss and at low frequencies is the predominant component of the total attenuation. With low values of Z_0 the $1/2(R/Z_0)$ is high and the pure wave becomes attenuated to a larger extent than would be the case with a larger Z_0 obtaining.

Also, if a circuit is carrying a current I, as this current is suddenly interrupted the maximum value of the oscillatory voltage that may be produced is equal to IZ_0; hence a small Z_0 may be beneficial if conditions are critical.

High Frequency and Low Voltage

The characteristics defining the performance of a h-v cable in service also may be taken as governing the design and operation of cables at high frequencies, although, upon increasing frequency, it is found that the roles they play in the wave propagation mechanism vary in magnitude and effectiveness to a greater or lesser extent, owing to the several requirements which distinguish the two modes of transmission.

In the transmission of intelligence from one place to another, the fidelity of the received signal is of more concern than the loss of energy, since the energy involved in any transmission of intelligence is extremely small when compared with the transport of large blocks of power demanded by industrial and household enterprises.

As mentioned earlier in the paper, the subject matter is restricted to the symmetrical configuration of a 2-element coaxial cable, so Fig. 1 in a very simple way again shows the h-f cables in question. In contra distinction to the h-v cables, the two coaxial conducting elements now form the circuit, one being the "go" conductor and the other the "return" conductor of the usual single-phase circuit.

The five transmission line equations, equations 5, 6, 13, 17, and 26, are applicable, and at high frequencies it follows from classical theory that

$$\alpha=1/2\frac{R}{Z_0}+1/2gZ_0 \tag{29}$$

as was the case with the pure transient wave associated with the impulsive energy of the lightning discharge. However, with an increase of frequency g has a more prominent effect on the attenuation constant and at very high frequencies the attenuation component due to the dielectric loss $(1/2gZ_0)$ may be as prominent or more so than the attenuation component due to copper loss $[1/2(R/Z_0)]$. The net effect is a relatively higher attenuation constant than obtains with a h-v cable line. Once again, insulants of high quality and stability, but not necessarily of the high electric breakdown strength required by h-v cable transmission, are a paramount desideration. Here the emphasis is upon the dielectric constant and power factor of the insulant.

Since the amounts of energy are relatively small, the attenuation constant is of utmost importance, and it therefore becomes desirable to operate a h-f cable at its natural load. That is to say, the load impedance must equal the characteristic impedance or nearly so, the cable is matched to its load. Hence

$$\begin{aligned}Z_0&=W\\&=\sqrt{L/C}\end{aligned}$$

the asymptotic value of the characteristic impedance versus frequency curve, and equations 7 and 13 become

$$e=E_R\epsilon^{\alpha x}\epsilon^{j\beta x} \tag{31}$$

from which

$$e=E_S\epsilon^{-\alpha x}\epsilon^{-j\beta x} \tag{32}$$

Similarly

$$i=I_S\epsilon^{-\alpha x}\epsilon^{-j\beta x} \tag{33}$$

and

$$\begin{aligned}p&=ei\\&=E_SI_S\epsilon^{-2\alpha x}\epsilon^{-j2\beta x}\\&=P_S\epsilon^{-2\alpha x}\epsilon^{-j2\beta x}\end{aligned}$$

The current, voltage, and power are thus decreased in accordance with the exponential function involving α, i.e., $\epsilon^{-\alpha x}$, the so-called attenuation factor. The highly significant effect of the attenuation of the waves as they proceed along the line is at once apparent, as is the similarity to the h-v cable case.

Another prime aspect bearing a close parallel to h-v cable design is the necessity of elimination of ionization within the insulating medium. It is a well-known phenomenon that ionization has a depreciating effect on the attenuation of the waves, especially at higher frequencies. And whereas this phenomenon would have a salutary influence on the behavior of h-v cables subject to atmospheric transient surges, it can cause a distortion of the signal transmitted at high frequencies which would be disturbing. This, of course, is apart from any chemical or electrical deterioration which would follow excessive or malignant ionization. Nonetheless, in some cables even at very low voltages a phenomenon, discernible by a band-pass fitter as noise, may be observed which cannot be distinguished qualitatively from internal ionization magnitude below which the ionization is innocuous in so far as chemical or electrical deterioration is concerned; it nevertheless cannot be tolerated for the reason already mentioned. As with h-v cables, so in h-f cables with solid dielectrics the formation of voids which may ionize under suitable conditions in service must be brought under control during the manufacturing process and be quantitatively held to within such limits that the magnitude of any subsequent ionization will be harmless in all respects.

The energy dissipated in the voids which are initially ionized is determined by the increment of the applied voltage over the ionization ignition voltage; and it may be that the life of either a h-v cable or a h-f cable, at stresses greater than the ionization ignition voltage, is a function of the excess of the applied voltage over the ionization ignition voltage. If this excess is definitely indicated and sufficiently great, the cable life is unquestionably finite and its mortality rate high.

Once again, owing to the fact that the energy involved at high frequencies is small, comparatively speaking, it is of interest to examine that equation which expresses the steady-state current rating of the cable. In so doing it will be appreciated that that part of the energy (or signal) which fails to appear at the receiving end is converted into heat energy and causes a rise in the cable temperature.

The same current rating equation applies,* namely equation 26, and when $Z_0 = W$ as obtains by matching the cable to its load, then

$$I_R^2 RRTH_0 \epsilon^{2\alpha x} + E_R^2 gRTH_{0D} \epsilon^{2\alpha x} = T_R \qquad (34)$$

or

$$I_R^2(RRTH_0 + Z_0^2 gRTH_{0D})\epsilon^{2\alpha x} = T_R \qquad (35)$$

or, according to the Mildner equation

$$I_R^2 R\left(RTH_1 \frac{\alpha_{c1}}{\alpha} + RTH_2 \frac{\alpha_{c2}}{\alpha} + RTH_3\right) + E_R^2 gRTH_{0D} \frac{\alpha d}{\alpha} = T_R \qquad (36)$$

So it becomes evident that at the higher frequencies where α assumes much larger magnitudes it must be taken into account in determining the current rating of the cable or the power rating. The influence of Z_0 on the current rating is also revealed by equation 35.

It so happens that for any given insulating material and a symmetrical arrangement of the circular elements Z_0 is a direct function of the geometry of the coaxial circles, and hence in practice is a more or less constant quantity over a range of cable designs, reaching a practical maximum of about 200 ohms. It therefore follows that the greater limitation on the current rating of the cable is the attenuation constant α, which, as already found, is made up of two additive components—one due to the copper loss and the other to the dielectric loss. The copper loss varies at any particular high frequency as the square root of the resistivity of conductor material and inversely as the diameter of the coaxial circles, while the dielectric loss for the same geometrical relationship varies as the power factor and dielectric constant of the insulating material. And, as already said, the characteristics of the insulating material which concern the dielectric loss become the greater criterion of successful performance of h-f cables as the frequency is increased.

Hence, as with h-v cable design, the capacitance parameter C assumes a limiting value because of its dependence on the dielectric constant of the medium. Where the amounts of h-f energy to be transmitted are not too large, a dielectric constant not much greater than 2 may be suffered, providing the power factor of the insulant is relatively low (=0.0003); the solid material polyethylene is invariably used nowadays in these applications.

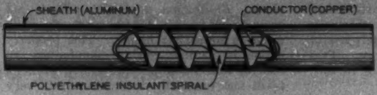

Fig. 4 (above). Helical membrane cable

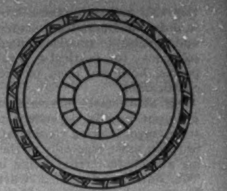

Fig. 5 (right). 120-kv oil-filled cable; outside diameter 2.65 inches

However, the efficient transmission of larger amounts of h-f energy, such as might be required for radio or video broadcasting, make the cable design more onerous. The symmetrical coaxial arrangements possess the maximum potential energy, and lowering the value of C, by increasing the diameter ratio, increases further the potential energy (or working electric stress) hence the power transmitted as well as the physical size of the cable. But the magnitude of ionization is related to the electric stress and must be kept to a minimum; consequently, there is a limit beyond which the potential energy or the working voltage cannot be raised without occasioning too bulky a cable.

Increasing the h-f energy also results in a greater power loss and higher cable temperatures as the current rating equation illustrates. Since the choice of highly conductive metals is fairly restricted, and because the asymptotic value of $Z_0 = \sqrt{L/C}$ is a fairly constant quantity consequent upon the usual load impedances involved, there remains but one other choice in designing h-f cables to carry economically the larger amounts of energy. This choice is a fairly obvious one suggested by the nature of the transmission line equations: it is to reduce to the attenuation constant to as small a value as possible.

The influence of Z_0 on the attenuation constant has been noted, and for any assigned value of Z_0 a minimum α obtains in the symmetrical coaxial arrangement for a specific ratio of the circle diameters. But this adjustment of the physical dimensions of the cable is not sufficient to result in an economically sound transmission system. Reducing the dielectric constant from somewhat over 2 to a value of 1 that obtains with air or other gases results in a decrease in attenuation of approximately 60 per cent. Therefore the solution of the problem lies in arriving at a practical cable design, mechanically robust and uniformly stable in performance, which would lend itself to commercial manufacture.

For a great many years now cable manufacturers all over the world have struggled with the problem of producing such a cable of the coaxial type. As may be appreciated, it involves the combining of the two unstable coaxial circles with the minimum amount of solid material and the maximum amount of gas into a permanently stable arrangement capable of retaining its initial symmetrical shape in any cross section throughout its duty in service and having, of course, a dielectric constant approximately equal to 1.

Fig. 4 illustrates the only cable design yet manufactured to conform to these qualifications. It was brought into commercial manufacture in England a few years ago as a result of considerable research and development work. Its design is unique and a fine example of the practice of science applied to cable making.

Fig. 5 shows a cross-sectional view of the 120-kv power cable for bulk energy transmission. As one examines closely the physical construction of these two cables, Figs. 4 and 5, some of their similarities and disparities become more tangible. In the one case—the h-v cable—the tapes are applied parallel to the longitudinal axis and in a helical formation; in the other the tape is applied at right angles to the longitudinal axis and again in a helical formation; but both make use of the tapes as their supporting structure to obtain and maintain the symmetry of the coaxial array which is so desirable.

◆

Discussion

F. H. Buller (General Electric Company, Schenectady, N. Y.): Mr. Short has presented a useful comparison between the characteristics of communication cables and power cables, and has emphasized points of similarity between these characteristics which do not manually occur to a cable engineer working in one field only. Such a comparison is valuable since it is often possible to get useful and constructive ideas from the practices which are current in a similar field. While the fundamental information is doubtedless available in the literature, it is very desirable from time to time that such comparisons be clearly drawn in order to stimulate constructive thinking, and possibly to provide immediately useful solutions to particular problems. Two points, however, seem to require further clarification.

---

* Heat flow deviates appreciably from the radial direction only when the insulant thickness becomes an appreciable fraction of the thermal wave length (thermal wave length = 1/2 electrical wave length).

Mr. Short states that conductor resistance R is not usually dependent upon steady-state current rating considerations but is a function more especially of the voltage rating and characteristic design in h-v cables. This statement is correct when conductors of the minimum permissible size are used. This minimum permissible size is a function of voltage rating (see the Association of Edison Illuminating Companies Specifications) and of type of insulation. However, the minimum permissible size usually corresponds to a very light load, a load which is, in fact, so light that it is seldom economical. The usual practice involves loads considerably greater than this, requiring the use of a much larger conductor in order to avoid overheating or excessive voltage drop. As a matter of fact, in power cable work the conductor size, and hence its resistance, is determined primarily by cable load since this is the factor which governs both heating and voltage drop; and it is only affected by the voltage rating and the cable design in so far as these factors affect maximum permissible temperature and thermal resistance.

Mr. Short states for all h-v cables of the usual conductor sizes a frequency of 60 cycles and close spacing of cables $\omega L = 1.9R$. A few spot checks indicate that this relationship does not appear to hold for single-conductor cables arranged on 6-inch centers, although it can be used as a very rough approximation for three conductor cables, or three cables pulled into one duct. Possibly, this is the thought which Mr. Short had in mind when he made this statement.

A. L. McKean (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): We should like to commend Mr. Short for his excellent summary of practical theory which emphasizes that 60 cycles and megacycles, in spite of wide divergence in frequency and application, obey the same fundamental laws of propagation and transmission.

We should like to take exception to Mr. Short's next to last paragraph which implies that the aluminum-sheathed cable with polyethylene helix separator shown in Fig. 4, developed in England, is the only design which provides a permanently stable, essentially air dielectric coaxial cable construction. There are others.

While polyethylene provides very adequate means of helical support in coaxial constructions, there is an even more suitable material available for such applications, namely polystyrene, in fully oriented tape form. Apparently, the author is not aware of styroflex, a coaxial cable which has gained world-wide recognition for its exceptional and uniform characteristics. The cable comprises a copper inner conductor, a helix of styroflex tape, and aluminum sheath outer conductor.

The reason for the exceptional qualities of styroflex lies in the stability of the styrene tape helix which surpasses polyethylene because of its extremely high modulus of elasticity. Elongation at 10,000 pounds per square inch is only 3.0 per cent; the yield point is somewhat higher. This property makes it possible, during manufacture, to control and maintain uniformity of helix pitch and pertinent diameters within very close tolerances. It also ensures stability of these uniform characteristics for the life of the cable.

Due to its outstanding properties, styroflex is presently being employed in many applications for which no other coaxial cable could be considered. Further, it is provoking reconsideration of many present-day coaxial installations and stimulating some entirely new fields of employment.

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.): Both power and communication cables are ways of transmitting energy and although both obey the general transmission equations, the contrasts in characteristics are as great as the difference in purpose of transmission. Efficient power transmission by cable requires that much more than 90 per cent of the transmitted energy shall arrive for use. Efficient communication transmission permits more than 99 per cent of the energy to be lost or utilized in transmission. In power, dielectric strength, cost of energy loss, and conductor heating by the losses are controlling; in communication these are negligible. In communication the one significant property is to transmit a sufficiently accurate replica, even though attenuated a thousandfold, of the originating complex wave. This compares with the power cable requirement of substantially zero attenuation and no essential problem of distortion.

For some communication circuits, the general equation of transmission may be used in simplified form, although often being required in complete form. Seldom, however, is it necessary to treat a power cable transmission with the use of other than the simplest equations and treating its distributed constants as lumped. In the power cable the one important exception to this simple method is where it is used as a carrier to transmit communication or intelligence or where nature chooses to impose transients (lightning) when the methods of analysis become those used for communication.

Many types of material are used by both types of cable. The knowledge of dielectric constant and dielectric power factor learned from one type of cable is useful for the other but even here the numerical values are variously and significantly affected by the difference in frequency. Similar problems arise on materials that are affected by moisture absorption.

H. D. Short: I should like to thank the discussers for their contributions, and in particular Mr. Buller and Mr. McKean for their kind remarks.

Mr. Buller has referred to the statement made concerning the parameter R and mentions the Association of Edison Illuminating Companies Specifications as specifying certain minimum conductor sizes for certain operating voltages. What I had in mind was specifically the higher voltage cables of all types; and the higher the operating voltage the more the statement I made becomes a truism. In point of fact, and in spite of standardizing specifications to the contrary, we have found it obligatory to examine closely the potential gradient across the insulant when recommending a cable design to operate at voltages greater than 30 kv to neutral. And of course in this regard it is not conductor size alone that operates, but the combination of conductor dimensions and insulant thickness in the usual logarithmic fashions. So that in contradistinction to Mr. Buller's feelings in the matter we must not only look at the conductor size from the standpoint of load but also for voltages above, say, 30 or 40 kv we must ensure that the stress at the conductor surface is not unduly high, and this is especially true when dealing with solid-type cables.

Mr. McKean has confined his remarks to the h-f class of cables. We are very much aware of the German h-f cable innovation known as the styroflex design. This cable first came to our attention during the last invasion of Europe by the Allied forces—installations of it having been discovered in use by Signal Corps officers. After the war the styroflex design was very carefully studied by the English cable firm which developed the helical membrane cable.

Mr. McKean misinterprets if he felt that I implied that an aluminum-sheathed cable was the only design which provided a permanently stable, essentially air dielectric coaxial cable construction. The context of the next to last paragraph cannot be so interpreted. Mr. McKean has missed the main point I was making for the helical membrane cable. It is, as stated in the paragraph preceding it, that the helical membrane cable combines, in comparison with any other coaxial cable not excepting the styroflex design, the minimum amount of solid material and the maximum amount of gas space per unit volume into a permanently stable arrangement. This volume ratio as delineated in the paper is of great importance in reducing the attenuation.

The other main feature I was emphasizing in the paper in these respects was the unique principle involved in the helical membrane design of applying a tape at right angles to the longitudinal axis while retaining the helical formation. In the styroflex design the tapes are used parallel to the longitudinal axes as is common practice in the industry, and the tapes are simply applied with 100-per-cent overlay, a long lay, and wide butt spacing; so that it is not possible to obtain in any given case the equivalent gas space which would obtain in the helical membrane counterpart. A comparison of the mechanical characteristics of polystyrene and polyethylene which Mr. McKean has attempted is beside the point, for obviously the helical membrane cable principle can be accomplished with either material or any other suitable dielectric for that matter. Or, to put it another way, the embodiment of the helical membrane design is not necessarily confined to any one material, such as polyethylene, although the higher melting point of polyethylene in relation to that of polystyrene does present some contemporary merit in favor of the former.

The great beauty and distinct advantage of the helical membrane cable in direct comparison with the styroflex cable is its simplicity in conception and manufacture, a fact which is reflected in their comparative costs as presently marketed.

An Investigation of the Capture Effect in a Narrow-Band Frequency-Modulated System

C. D. HEDGES
ASSOCIATE MEMBER AIEE

CAPTURE effect in frequency-modulated (FM) radio transmission is that phenomenon whereby the stronger of two signals increases its predominance over the weaker signal on the same frequency in a receiver so that the weaker signal is eliminated from the receiver output. The transition in control can be very sharp when one signal becomes even slightly stronger than the other signal. That is, a small differential in radio-frequency input levels of the desired signal to the interfering signal results in a much higher ratio of signal to interference in the audio output. This characteristic of some FM systems permits the use of many more broadcast stations within a given area operating on the same carrier frequency than is possible with amplitude modulation (AM).

The amount of capture effect present in FM equipment is dependent, among other things, on the total channel bandwidth utilized. About 10 years ago, FM communication equipment was recommended for power-line carrier use; a major feature was that it possessed capture effect. This phenomenon supposedly would make it possible to work two channels back-to-back at the same station on the same frequency with less isolation between them than would be required for conventional AM channels. From a preliminary study made by the author, it was concluded that very little, if any, capture effect was present in narrow-band equipment. This is also the conclusion reached by others in previously published literature.[1,2] The investigation reported in this paper has been made to study capture effect as it relates to narrow-band FM systems used in the power-line carrier field. It was concluded, after the investigation, that a narrow-band FM system is only slightly better than an AM system of the same bandwidth with respect to rejecting interfering signals or noise.

Capture Effect Theory

From an explanation on why capture effect is present in a wide-band system, it will become evident that this phenomenon is much less effective in the narrow-band systems. When two signals, desired and interfering, pass through an FM receiver, both phase modulation (PM) and AM are produced. The AM would ordinarily be heard as a beat note in an AM receiver but the limiter circuits in the FM receiver eliminate the variation in signal due to AM. The undesired PM is not so easily eliminated. The PM results in an indirect FM signal which produces an audible output at the discriminator and the receiver output. In wide-band FM systems this interference cannot actually be eliminated but its effect can be minimized by making this undesired output appear insignificant when compared to the desired audio signal.

If the PM resultant signal is examined, it is seen that it can be represented by two carrier signals giving a resultant having the average frequency of the stronger but having its phase shifted plus and minus around its mean value at a rate equal to the difference frequency between the two carrier signals. PM may be illustrated by referring to Fig. 1. The desired carrier phasor continuously rotates through 360 degrees. The weaker undesired signal rotates relative to the desired carrier at a frequency equal to the difference frequency (F_D-F_I). AM is produced as shown. As the undesired phasor rotates around the desired phasor, PM is produced between the limits A and B. The faster the undesired phasor rotates or the faster the rate of phase change, the greater the FM. Thus, as the beat frequency increases, PM increases and therefore the undesired audio output increases. Thus, it can be shown that the degree of the indirect FM formed from PM depends upon the expression $(\Delta\theta)\,(F_D-F_I)$.[3] As already stated, F_D-F_I is the difference frequency between the two unmodulated carriers in cycles. The other factor $\Delta\theta$ is given in radians and is dependent upon the relative amplitudes of the desired and undesired carrier signals. Assume that the two signals differ in magnitude by a ratio of 2 to 1. The maximum value of $\Delta\theta$ is 26.5 degrees $[\tan^{-1}(I/D)]$ which is 0.464 radian. Assume that the difference frequency between the two carriers is 2,500 cycles. Substitution of these values into the foregoing expression results in a frequency shift of 2,500×0.464 or 1,160 cycles. The frequency variations shift at a rate of 2,500 cycles a second over a maximum shift of 1,160 cycles.

At this point it is desirable to compare the characteristics of a wide-band FM system such as is used in broadcast service with narrow-band systems as used in power-line carrier. The maximum deviation for carrier systems is approximately 2,500 cycles, and carrier FM receivers have a bandwidth of approximately 5 kc. In comparison, an FM broadcast station may employ a maximum deviation of 75 kc and the broadcast FM receiver bandwidth is approximately 150 kc. Power-line carrier systems deviate 2,500 cycles to produce 100-per-cent modulation, but in the wide-band broadcast system the carrier must deviate 75 kc to produce 100-per-cent modulation.

Returning to the example given for the conditions assumed, a shift of 1,160 cycles was present because of PM between the desired signal and the interference signal. In a wide-band receiver, the interference produced by a shift of 1,160 cycles is insignificant when compared to the audio signal developed by a swing of 75,000 cycles. As the ratio of the amplitude of desired to interference signal at the receiver input is increased or the frequency difference between the two signals decreases, the suppression of the interference signal improves. Thus, the use of wide-band FM swamps the small FM

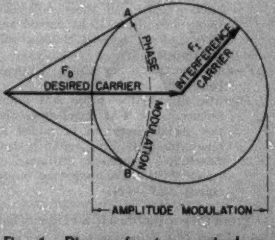

Fig. 1. Diagram for two received unmodulated carriers of different frequencies F_D and F_I

Paper 55-79, recommended by the AIEE Carrier Current Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 21, 1954; made available for printing November 18, 1954.

C. D. HEDGES is with the Westinghouse Electric Corporation, Baltimore, Md.

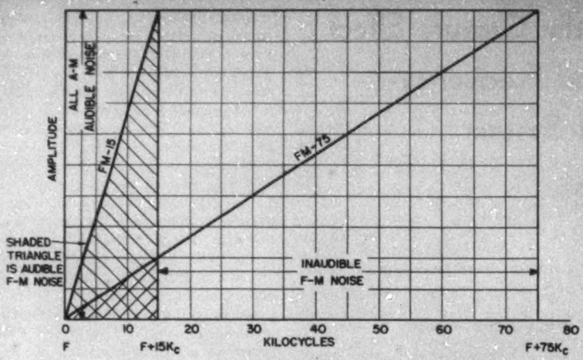

Fig. 2. Noise diagram for FM and AM receivers for various FM deviation ratios

signals developed indirectly from the interference. As the deviation ratio is decreased, the effect of the interference because of PM becomes more and more important. In a power-line carrier FM system, where the maximum shift is 2,500 cycles, it is evident that the interference caused by the calculated shift of 1,160 cycles would be too high to tolerate, almost 50-per-cent modulation. This is the same condition that exists in an AM system when the signal-to-interference ratio is 2 to 1 at the receiver radio-frequency input. Wide-band FM is required for minimum interference, and in these cases capture effect is present.

The relationship of I (interference) to D (desired signal) and frequency deviation can be shown to be as follows:

$K_1=(I/D)\,(100)$, interference modulation in an AM receiver in per cent

$K_2=(I/D)\left[\dfrac{F_D-F_I}{\Delta F}\right]\,(100)$, interference modulation in an FM receiver in percent

I = interference level

D = desired signal level

(F_D-F_I) = frequency difference between desired and interference unmodulated signals. All those difference frequencies above 15 kc should not be considered because the ear will not respond

ΔF = maximum frequency shift. Channel bandwidth equals $2\times\Delta F$

I/D = ratio of amplitudes for AM interference. For FM interference the two signals have to be added in quadrature. If, e.g., $I=0.5D$, then $\Delta\theta=\pm 26.5$ degrees or 0.464 radian $(\tan^{-1} I/D)$. The frequency swing equals $\Delta\theta(F_D-F_I)$

From these equations it is evident that wide-band FM definitely has an advantage over an AM system. If the maximum deviation is 75 kc, and (F_D-F_I) is 15 kc, the resulting interference in an FM receiver would be only 20 per cent of that obtained with an equivalent AM receiver. If the two signals have the same carrier frequency, then no audible beat effect can exist and the equivalent FM signal is zero. If the two signals differ slightly in frequency, the resulting interference is completely outweighed when the maximum deviation is 75 kc. This is an important feature of wide-band FM since the well-known beat whistle interference in an AM receiver makes reception almost impossible. However, in narrow-band FM where the deviation is limited to a low value—2,500 cycles in the case of FM power-line carrier transmitters—this advantage is greatly reduced and the capture effect of narrow-band FM over AM is very slight.

The preceding discussion was used to illustrate capture effect for the simplest case where two unmodulated carriers of different frequencies F_D and F_I arrive simultaneously in an FM receiver. For the condition when the desired and interfering carriers are modulated, PM is produced between the various desired and interfering side bands. The analysis of the interference for this case can be made by treating the resulting signals as instantaneous carrier signals (F_D-F_I). A rigorous analysis is given in Hund's book[3] on FM for this condition. See Table I for actual listening test comments made on a carrier system with both carrier signals modulated simultaneously.

Interference from Noise

In carrier systems not only is interference present from other carrier signals but there is also transmission-line random-type noise plus impulse noise due to electric storms and other sources. The analysis of this is the same as the previous discussion on capture effect theory. The reaction between each noise voltage and the carrier again produces AM and PM in which case the AM is removed by effective limiting. Since each noise signal is the same as an interference signal, then as the difference frequency increases (F_D-F_I) the interference from PM increases. This plots a triangular noise response for an FM receiver as shown in Fig. 2. In an AM receiver, each noise voltage of a different frequency will mix with the AM carrier to form a beat note. The amplitude of each beat note is the same because all distributed noise voltages have approximately the same strength and therefore, in place of a triangular noise response, there is a rectangular response. For example, a single interfering wave at the band edge in FM would give an output amplitude as great

Table I. Listening Test Comments with Transmitters T_1 and T_2 Modulated Simultaneously. See Fig. 3 for Block Diagram

T_1/T_2: Radio-Frequency Carrier Level Unmodulated, Decibels	Condition A: Unmodulated Carriers Initially Adjusted for a 300-Cycle Beat Note	Condition B: Unmodulated Carriers Initially Adjusted for a Zero Cycle Beat
0	With both signals on, neither is understandable.	
6	The desired signal T_1 is understandable but rough and distorted. Undesired signal not understandable but quite loud.	The desired signal over-rides the undesired and it is readable with practically no difficulty. The undesired signal is quite loud. When the desired signal ceases modulation, the undesired signal is also readable with practically no difficulty.
12	The interference is not tolerable but the desired channel can be understood quite well.	Desired signal is readable with no difficulty but interference is still too objectionable.
20	With both signals on, the undesired still comes in and can be heard as interference but it has practically no effect on the understandability of the desired signal. The undesired signal is a nuisance, however, along with the tone and could not be tolerated.	The desired signal is perfectly readable but the undesired signal is objectionable in the background.

Fig. 3. Block diagram of system used to obtain listening test comments

as the same noise signal located anywhere in the AM passband. For an FM system, the suppression of noise is directly proportional to the deviation ratio. In Fig. 2, the FM-75 receiver actually accepts noise out to 75 kc and it has the usual FM triangular noise characteristic. The human ear, however, is only sensitive to frequencies within the range of audibility, up to around 15 kc, and rejects everything else. The maximum height of the audible part of the FM-75 triangle corresponding to voltage is only one-fifth of the height of that for an FM-15 triangle. Such being the case, the FM-75 advantage over FM-15 is appreciable. Then, for this consideration, it may be said that wide-band FM is superior to narrow-band transmission, but only if the input desired signal to distributed noise ratio is initially large. For impulse noise, the carrier level must be even higher than it is for distributed noise.

The requirements for a carrier communication system include the specification which requires that the equipment operate over long channels in the presence of high noise interference usually encountered on these long lines, in which case the desired carrier-to-noise voltage ratio is low. In a wide-band FM system when the signal is stronger than the noise, the audio output signal-to-noise ratio is even better than the input radio-frequency ratio but, conversely, if the noise is greater than the signal at the input, then the noise-to-signal ratio at the output is high. That is, if the noise is higher than the desired signal, the wide-band set will be captured by the noise. This would swamp the desired signal which is highly undesirable. The wide-band set shows favoritism. The ability of the narrow-band FM to reach down into the noise means that there is no capture effect because both the signal and the noise are received, neither being favored and the other excluded. Because this characteristic is not in wide-band FM, its use on a power-line system for the purpose of utilizing the capture effect feature would prove very impractical.

Experimental Results

Listening tests were conducted on standard Westinghouse type-*FD* FM equipments. Two transmitters and one receiver were employed with all units tuned to 40 kc. As previously stated, the maximum audio modulating frequency was restricted to 2,500 cycles. The maximum deviation of the carrier is 2,500 cycles for power-line carrier transmitters so the deviation ratio for this equipment is 1.

The listening test comments listed in Table I are significant because the final decision as to whether a system is actually workable is dependent upon favorable listening comments. Two conditions are included. One condition is when both unmodulated carriers are exactly on the same frequency, and the second condition is when a 300-cycle beat note exists between the carriers. This latter data are included because of the allowable drift specifications on transmitters installed in the field. From Table I it can be concluded that a reduced quality service, such as emergency voice communication, in the presence of an interference signal is possible provided the desired modulated carrier is 6 decibels or more stronger than the undesired modulated carrier. To say that communication is possible under these conditions means that the desired signal is understandable with practically no difficulty in the presence of an undesired modulated carrier, but the communication is not of the same high quality as provided by standard voice communication channels. The audible crosstalk is at such a high level that it would become annoying on constant usage. Also, when the undesired carrier is modulated and the desired carrier is not modulated, the undesired channel can be understood provided the undesired carrier level is not more than 20 decibels below the desired carrier level. This means that a listener on a desired channel would hear the desired signal satisfactorily in the presence of a modulated interference signal which results in crosstalk, but the listener will also hear the undesired channel satisfactorily when the desired channel is not modulated. This is very distracting to a conservation, but, as stated previously, emergency communication would be permitted. Likewise, an equivalent AM system with the same amount of isolation could be used as effectively.

Conclusions

There is little, if any capture effect present in the narrow-band FM equipment and this is one of the reasons that the equipment is suitable for power-line carrier application. In some applications the equipment is required to operate over long transmission lines where the noise level occasionally approaches the desired signal level. The ability of the narrow-band receiver to receive both the desired signal and the noise, neither being favored, allows the signal to be understood in the presence of the noise. In a wide-band FM system, there is appreciable capture effect which means that the over-all result is to receive the larger signal and swamp out the low signal. However, if a wide-band FM system was applied to carrier application and the noise at the receiver input was greater than the desired signal, then the noise would be received and the desired signal eliminated. Thus, for this reason, the use of wide-band FM for carrier application would be very impractical.

Emergency voice communication in the presence of an interference signal is possible provided the desired carrrier is 6 decibels or more stronger than the undesired carrier. The audible crosstalk is at such a high level for this condition that it would become annoying on constant usage. For acceptable voice communications, more than a 20-decibel difference in level between desired and interfering signals is necessary.

Discussion

F. C. Krings (General Electric Company, Schenectady, N. Y.): The author should be commended on this addition to the application practices on power-line carrier. The listening tests contained in Table I will be of considerable value when it is desired to repeat or reuse a frequency which is already in use for FM carrier telephony. The listening tests are much more illuminating than the numerical examples used in the paper; in fact, the example in the section on "Capture Effect Theory" may lead one to an erroneous conclusion when modern carrier equipment is considered. The expression for the degree of indirect FM formed from PM of the carrier is stated in the paper as the product of the difference in signal strength times the difference in frequency. If two crystal-controlled carrier equipments are used, the maximum difference in frequency would be only 200 cycles instead of the 2,500 cycles used in the example. Then if a difference in signal level of 20 decibels is assumed, the resultant maximum shift produced by the interference is only 20 cycles. In comparing this with FM broadcast, as was done in the paper, the percentage shift is only 0.8 per cent for the carrier and is less than the 1.55-per-cent shift for the FM broadcast in the example in the paper which was labeled as insignificant.

C. D. Hedges: Mr. Krings has brought up a factor which must be clarified. The numerical example assumed in the paper was used to illustrate the degree of capture effect present in the narrow-band power-line carrier system as compared with the wide-band system under the same conditions. These conditions were that the difference in signal level between the desired signal F_D and the interfering signal F_I was 6 decibels, and also that the factor F_D-F_I was 2,500 cycles. This results in a shift of 1,160 cycles at a rate equal to the difference frequency. For the power-line carrier system, where the maximum deviation is 2,500 cycles, the interference produced is $(1,160\times100)/2,500=46.6$ per cent, which is approximately the 50 per cent stated in the paper. For the wide-band case, where the carrier deviates 75,000 cycles, the interference produced is $(1,160\times100)/75,000=1.55$ per cent.

In the example used by Mr. Krings, the difference in signal level is 20 decibels and the factor F_D-F_I is 200 cycles. It is true that the resultant maximum shift produced by this interference is only 20 cycles. For these conditions, the power-line carrier system will be subject to $(20\times100)/2,500=0.8$-per-cent interference, as compared to the desired audio output. For the wide-band FM system, the degree of interference is $(20\times100)/75,000=0.0267$ per cent.

Note that in both examples the degree of interference for the wide-band system is much less than that for the carrier system. The 0.8-per-cent value calculated by Mr. Krings for the carrier system is not directly comparable to the 1.55-per-cent value that can be calculated from the example in the paper because the conditions are not the same. In either case, however, it should be brought out that there is a significant improvement in the suppression of interference by the wide-band system over the carrier system when the same conditions are assumed. As has been previously stated, this was the reason for the numerical example.

Aluminum-Sheathed Power Cable

W. A. DEL MAR
FELLOW AIEE

E. J. MERRELL
MEMBER AIEE

IN 1886 Charles Hall developed the electrolytic process which made possible the economic production of aluminum. The process entails the consumption of about 10 kw-hours of electricity per pound of metal, and this energy represents about 20 per cent of the cost of aluminum.[1] The first commercial installation of aluminum-sheathed cable in the United States was a limited amount of telephone cable employed in 1932 on the dirigibles Akron and Macon.[2] Applications as cable sheathing were sporadic and of an essentially exploratory nature, until the threat of lead shortage in recent years sparked relatively comprehensive European usage in both the power cable and communication cable fields.[3]

In 1952, commercial production of standard lengths of aluminum-sheathed communication and power cable was undertaken at the Habirshaw Division of the Phelps Dodge Copper Products Corporation. This cable has ranged in diameter from 3/8 to $3^1/_8$ inches and has been shipped on reels in 1,000-foot lengths. Table I lists the pioneer power cable installations in the United States. When corrosion protection is required, an extruded jacket of black polyethylene is applied directly over the aluminum sheath.

Sheath Manufacture

Current manufacturing, in America, employs the draw-in and sinking method, and 2 years of experience on a considerable scale has led to the following procedure. Billets of aluminum are extruded and the tube produced is wound in long continuous lengths (multiples of 1,000 feet) on extra-large reels. These are pressure-tested and vacuum-treated, then charged with dry gas and sealed until used for cable sheathing. In the sheathing process, the required length of tube (up to 1,000 feet at present) is drawn out straight and, again, pressure-tested with dry gas. Next the cable core is drawn in. Finally, the tube is passed through a sinking die to form a suitably close fitting sheath.

The hardness or stiffness of the sheath differs at a press stop. As a result, the larger sizes tend to wrinkle some in this area when being wound on or off a reel. A practical solution to this problem is a temporary binding of two metal tapes applied over the press stop for a length of 1 foot as the cable passes from the sinking die. Such a binding is shown in Fig. 1. This is removed after installation in the field except, of course, when a polyethylene jacket has been applied over it.

The comparatively high hoop strength of aluminum sheath would seem to permit significant reduction in thicknesses from those customary for lead sheaths. However, the basic practical factor in determining sheath thickness is resistance to corrugating under normal handling procedures. This requirement results in aluminum thicknesses not far from those used for lead sheaths, being actually greater for the largest diameters. However, with the rather considerable support afforded by an extruded polyethylene jacket, reductions in aluminum thicknesses can be made to bring them close to the limit imposed by hoop stress. This is shown in Table II.

The ultimate aim for aluminum sheath production, as for lead, is continuous and direct extrusion, from press onto

cable core, of a seamless tube free of press stops; in other words, a screw press. Such a machine does not appear feasible at present. However, the newer European high-capacity ram presses are capable of being recharged with preheated billets within seconds so that the direct application of aluminum sheath to commercial lengths of cable is a step closer. On the other hand, press stops and billet junctions remain as significant factors for consideration. Achievement of technically satisfactory procedures in this respect is important economically.

Solid-Type Paper Cable

Necessarily, when the sheath is applied on solid-type paper cable, a small positive clearance is required to enable accommodation of impregnant expansion on temperature cycle. Otherwise, because of the high strength of the aluminum, excessive internal pressure would develop. The clearance is a function of impregnant volume and core diameter. If the cable is not shielded, this space can be ionized. Even if the cable is shielded, impregnant can migrate from the dielectric wall into the space so that some ionization may result within the insulation. Thus, aluminum sheathed solid-type cables may not exhibit as low ionization factors as newly manufactured leaded cable.

Of course, upon the first temperature cycle of any magnitude to which a leaded solid-type cable is exposed, impregnant expansion permanently enlarges the lead diameter. This results in a void volume comparable to that which must be built into the aluminum-sheathed cable originally as it is manufactured. That the void volumes are essentially equivalent is shown by the fact that aluminum-sheathed paper cable exhibits normal solid-type cable characteristics in standard accelerated load-cycle testing procedures. For example, the power-factor and ionization characteristics remained stable in the following load-cycle test run at double rated voltage on a 60-foot length of 3-conductor, 500,000-circular-mil 13.2-kv cable with an 80-mil sheath and a 90-mil polyethylene jacket. The test consisted of daily heat cycles accomplished by loading the conductors for 8 hours of each day. Voltage was on continuously. There were in succession 4 cycles to 60 degrees centigrade (C), 4 to 80 C, 4 to 100 C, 4 to 120 C and 50 to 85 C. The sample was terminated in a trifurcator fitted with porcelain potheads, laid horizontally and level with the cable run so as to prevent pothead oil from migrating into the cables. The trifurcator, shown in Fig. 2 was wiped to the aluminum sheath. Radial power factors, measured at 80 C, after the load cycle test were indistinguishable at the wipe and on the cable run.

Joining Aluminum Sheath

Joints in aluminum cable sheaths can be made by wiping, welding, or by mechanical means. Mechanical connections, i.e., flare, ferrule, threaded, with or without supplementary *O*-ring or gasket seals, are adapted to some branches of the communication field because cable dimensions are standardized at a few sizes. However in the power cable field the multiplicity of sizes requires that each application be considered separately. Welding, perhaps the most effective means of making a joint, particularly for paper cable, is in about the same category as mechanical joints for power cables. The welding is done with a tungsten arc in an argon or helium atmosphere. Argon is preferable for cable sheath work because it affords better control of the weld pool and arc. There is less clouding and the metal stays brighter in the argon envelope, enabling the welder to see the weld pool more clearly than in the case of helium. The welding head has a cup and a tungsten electrode which is water cooled to keep the electrode from melting. Flow of the argon or helium out of the cup is maintained during welding so that the arc and pool are surrounded excluding

the atmosphere. Fig. 3 shows a typical portable tungsten arc welder and accessories.

Wiping has been a time-honored procedure for joining the lead sheaths of power cable. Not only has it been effective but substantially the same technique is adapted to all sizes of cable. However, a prerequisite to a successful wipe is a successful and stable tinning. The tinning must be compatible with the sheath and the wipe metals. The tinning and wiping operations must not have a deleterious effect on the dielectric. Several aluminum tinning recommendations were tried on aluminum sheath without success, according to these criteria. Cadmium-zincs gave excellent bond strengths, but the tinning temperatures were too high, scorching several layers of paper except when the operation could be accomplished very quickly. The requisite speed could not be attained in the field. Tin-zincs, while effective on tube and sheet, were unreliable on cable. Clean tinning was virtually impossible to sustain while wiping.

The use of flux-assisted tinning was considered undesirable for paper cable applications, since fluxes for tinning aluminum are characteristically polar. Also, because of the exceedingly active nature of aluminum, chemically, it was deemed unwise to take a chance of leaving polar residues in the wipe region. Actually, when fluxes were employed to assist tinning, the tinning usually became unstable during wiping.

A screening test technique employed to identify the less promising tinning mixtures is illustrated in Fig. 4. Aluminum rings, 1/2 inch wide with a 140-mil wall and a diameter of $3^{1}/_{8}$ inches, were used to test bond strength. A flat, measuring 1 by 1/2 inch was made by pressing the ring over a jig 1 inch wide. The flats on a pair of rings then were filed clean and tinned with a test mixture and then coated with a film of wiping solder. The tinned surfaces of the pair were brought together under hand pressure and heated with a torch to complete the seal. Fig. 5 shows a pair of rings sealed and ready for test. The bond strength was measured at room temperature as newly made, and after aging at 90 C and 100-per-cent humidity. Fig. 6 shows a specimen in the tensile machine which applied loading at the rate of 1/4 inch per minute.

The most effective tinning solder worked with is a tin-zinc-lead combination (77.18, 20.47, 2.25). It tins cleanly at a temperature low enough not to scorch the paper tapes. No flux is necessary. It has good bond strength and is stable at wiping temperatures.

The following procedure is employed:

1. Make certain the sheath is free of oil film and like contamination. Stearine is not to be used on the aluminum.

2. Use a smooth file to remove the aluminum oxide from the sheath surface to be

Fig. 5. Test specimen prepared for screening test

Fig. 6. Testing screening specimen after aging

Fig. 7. Aluminum sheath filed preparatory to tinning

Fig. 8. Tinning the filed aluminum sheath with special solder

tinned. The filed length, as illustrated in Fig. 7, should extend well beyond the length to be wiped. This is done to minimize the possibility of interfacial corrosion at the aluminum surface, which under wet conditions and particularly in the presence

Fig. 9. Coating special tinning solder with wiping solder

of electrolyte can develop sufficient lifting force to separate a wipe.

3. Tin the entire filed section immediately, while heating the sheath with a gas torch and rubbing the aluminum surface vigorously with the stick solder; see Fig. 8.
4. Before tinning cools, coat with wiping solder (40–60); see Fig. 9.
5. Cover tinned sheath with oil-proof tape, e.g., polyethylene tape.
6. Build splice, removing sheath with a lead knife.
7. Place previously tinned sleeve in position.
8. Using ladle technique and cloths free of stearine, pack wiping metal. The wiping cloth is not to contact the tinned surface of the sheath. Discard overflow as this is likely to be embrittled by contamination with aluminum oxide. Keep pot at 290C±10.
9. Dress wipe with a hot soldering iron.

Cable Bend Tests

While for short-time tensile strength tests it is possible to make wipes stronger than the aluminum tubes which they join, this has not been the case for the most part in cable-bending tests. Moreover, when the wipes are kept wet, failure occurs by corrosion at the aluminum and tinning metal interface. Also, bend tests on welded joints show that much work must be done before the potential manhole bend life of aluminum sheath is realized.

Two test setups were employed. In one, a 5-foot sample was trained in an arc with a radius of 42 inches, terminations being a wiped pulling eye and a splice sleeve at the opposite ends. The sleeved end was held stationary in a swivel grip, and the pulling eye end was subjected to a 1-inch travel while free to swivel. In the second setup, Fig. 10, the sample was trained as for a normal manhole installation; 24-inch offset, bend radius of 12 times the diameter, with the splice centered. Both ends were wiped into pulling eyes, each of which was simultaneously subjected to 1-inch travel, opposed, but free to swivel. The splice was carried on a tripod ball-bearing mount and permitted to seek its position freely.

All samples were trained to forms so as to avoid any concentration of change of curvature. Strain in the outer skin was calculated from deflections measured with a micrometer mounted on a 6-inch chord. Each sample was charged with gas at 5 pounds per square inch, and then subjected to a continuous bend test at the rate of 1 cycle per minute. When a fatigue crack developed, the charge of gas would leak out and a relay actuated by the drop in pressure would stop the bender. A mechanical counter kept track of the number of cycles.

Bend-test results are summarized in Table III. These data emphasize the advantages of triplexing aluminum sheath cable when possible. Thereby, not only is an increased sheath life assured but more significant is the increased life which may be expected of wipes as a result of the inherently lower unit stresses on load cycle. In general, these tests indicate that the problem of designing joints for duct cables is yet in the developmental stage.

Installation Procedure

It has been the authors' experience in preparing samples for manhole bending

Fig. 10. Wiped joint sleeve on manhole bend test

tests that cables up to a diameter of approximately 1 inch may be trained to a smooth curve with a radius equal to 12 times the diameter of the cable, and that for larger cables a training radius of about 15 to 25 times the diameter should be employed. These are training radii, not radii around which cables may be pulled and then straightened during installation. Thus, when pulling cable around bends, the radius should be as generous as pos-

Table III. Bend Tests on Aluminum-Sheathed Paper Cable at Room Temperature

Test Setup	Sheath Wall, Mils	Cable Outside Diameter, Inches	Strain in Sheath, Per Cent	One-Minute Cycles to Failure	Comment
5-Foot curve	65	1.16	0.26	36,644	Length of cable without a splice.
			0.27	12,736	Wiped splice on sleeve side of center Lead sleeve. Wipe cracked adjacent to sheath.
			0.37	19,678	Wiped splice on eye side of center. Lead sleeve. Cable sheath ruptured inside curve at center.
			0.42	3,224	Wiped splices on both sides of center. Lead sleeve. Cable sheath ruptured inside curve at center.
			0.17	678	Wiped splice in middle. Lead sleeve. Splice sleeve failed in middle.
Trained			0.14	4,053	Wiped splice in middle. Lead sleeve. Wipe fatigued at top adjacent sleeve.
			0.14	1,023	Wiped splice in middle. Lead sleeve. Splice sleeve failed at one end.
	80	2.13	0.12	150,000+	Length of cable without a splice.
			0.597	795	Wiped splice totally restrained. Lead sleeve. Cable sheath ruptured in bend adjacent to eye.
			0.214	9,101	Wiped splice in middle. Aluminum sleeve. Wipes kept wet. Tinning corroded through.
			0.260	3,942	Welded splice in middle. Aluminum sleeves. Sheath fatigued adjacent to weld.
			0.106	4,916	Welded splice in middle. Aluminum sleeves. Sheath fatigued adjacent to weld.

Fig. 11. Shipping length of aluminum-sheathed cable with wiped pulling eye and soldered end seal

Fig. 12. Experimental installation of polyethylene-jacketed aluminum-sheathed aerial cable

sible and not less than the shipping drum diameter. Requisite training curvatures can be accomplished most expeditiously with guide templates or standard tube-bending equipment.

Otherwise, installation procedure follows practices customary in handling leaded cable. The cable is shipped with standard pulling bolts or eyes and caps, as shown in Fig. 11. Light braking on the reel flange, with boards, usually affords ample tension to straighten satisfactorily power cable at least up through 2-inch outside diameter. For aerial installations where appearance is important, necessary braking of the reel may be kept to a minimum by employing a simple box straightener, mounted as close to the reel as feasible. The recommended box length is 25 times the cable diameter, with an inside clearance approximately 3 per cent of the cable diameter. A wipe of mineral oil on the cable as it enters the box will minimize friction, thereby reducing pulling tension.

Standard 2 by 8 plank is ample for a 3-inch outside-diameter cable straightener. Constructing the box with carriage bolts facilitates threading. Thus, a length of cable equal to the length of the box plus pulling grip may be straightened against a board on the ground, then swing into the opened box, the top of which is then secured by bolting. The straightener may be rigged to traverse the reel as the cable is unwound. Since the box straightener described offers little braking and can be restrained with light tackle, these are relatively simple procedures.

The high order of self-support exhibited by aluminum sheath cable permits wide spacing of trolleys and aerial suspensions. In an experimental installation a 3-conductor 500,000-mil 13.2-kv cable was pulled on trolleys spaced 15 feet apart, and the sag was insignificant as shown in Fig. 12.

Corrosion Protection

Protection of wipes and sheath from moisture and other sources of corrosion is mandatory for aluminum-sheathed cable. Table II gives the thicknesses of extruded polyethylene jacket, recommended as corrosion protection for aluminum sheathed power cable. Some million feet of paper cable have been fabricated with polyethylene jacket over lead sheath during the past 8 years. The self-lubricating property of polyethylene together with its high modulus of elasticity permit pulling dry. However, if minimum pulling tensions are desired, Bentonite polyethylene cable pulling compound is recommended. Polyethylene is admirably suited as a protective jacket for aluminum sheath, since it is both light and waterproof. The latter property is most important, because the most prevalent and perhaps the most dangerous source of corrosion is moisture in the presence of a restricted or differential supply of oxygen. This condition is almost certain to result when absorbent materials such as paper, cotton tape, wood clamps and the like are in contact with aluminum in damp locations. Under such circumstances, deep local pitting occurs very rapidly even though the water exhibits a virtually neutral test.[3] The process is essentially the formation of a local electrolytic cell. As a result of this cell formation, a very small pit is formed in which the anode is at the base. Aluminum in the pit is converted to oxides, hydroxides or salts and by progressive action the depth increases, the attack being concentrated at one place. A characteristic feature is that there may be a few tiny holes which penetrate the sheath completely, but little or no general superficial attack. This deleterious reaction becomes impossible with a polyethylene jacket because of the complete exclusion of moisture at the jacket-sheath interface; and the excellent structural properties of this material permit clamping directly upon the polyethylene, separating water-filled crevices and other dangerous moisture-containing zones in accessory hardware from the aluminum.

Economics of Aluminum Sheaths

When studying the economics of aluminum cable sheaths, it is important to remember that the cost of a sheath depends greatly on the process by which it is applied to the cable. At the present time, the only method available in the United States is by drawing the cable core into an aluminum pipe and swedging the pipe down to fit the core. This involves three processes, the extrusion of the aluminum tube, drawing the cable into the tube, and swedging. Aluminum tube, as furnished by the leading aluminum companies, costs several times the market price of ingot aluminum. Aluminum sheathed cables made by this process obviously do not realize the ultimate economic possibilities.

However, because of the work being done in Europe with presses designed to extrude aluminum directly over a cable core, in one operation, aluminum sheaths

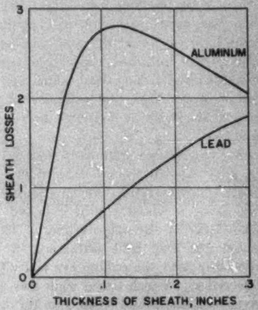

Fig. 13. Relative sheath losses versus thickness of sheath for aluminum- and lead-sheathed cables

may be put in a much more favorable economic position. Therefore, in a general appraisal of such cables it seems proper to give aluminum the benefit of the expected economic advantage of direct extrusion.

Three-conductor cables with aluminum sheaths have much higher sheath losses than cables with lead sheaths. The following study relates to cables of that type. The same principles may be applied to other types.

When cables of equal conductor sizes are compared, the lower ampacity, i.e., current-carrying capacity in amperes of the aluminum-sheathed cables because of their greater sheath losses results in lower I^2R losses in the conductors. The combined cost of these losses and the cost of the cable, by whatever method the fixed charges and operating charges are combined, are likely to be favorable to the aluminum sheathed cable. Aluminum-sheathed cables equal in ampacity to lead sheathed cables must have larger conductors and, consequently, sheaths of greater conductance in which losses are greater. It is to this more important case that this study is now addressed.

The first problem is the determination of sheath losses. There are a number of references on this subject.[4–7] The method used is that given by R. W. Burrell[7] because of its simplicity, see the Appendix. Such an equation gives a curve of the shape shown in Fig. 13 from which it appears that the losses increase rapidly with thickness of sheath and, after attaining a maximum, fall off slowly. The maximum for lead is far beyond any practical thickness.

The purpose of an economic study is to compare the present worths of expected future expenses under alternative plans. In this study, the alternative plans call for lead-sheathed and aluminum-sheathed cables of equal ampacities. The expenses to be considered are the costs of the two cables and the cost of equipment to supply the energy losses therein, both of which are taken to be capital charges and the annual costs of energy losses in conductors and sheath, both of which are operating charges. These have to be combined to obtain a total and the usual procedure is to take a certain percentage of the capital charges to include interest on investment, depreciation, taxes, and insurance. This percentage is added to the annual charges and the totals for the two plans are compared. Some engineers do not consider the cost of equipment to supply losses as a legitimate capital charge and prefer to use the sum of the fixed charges on the cables only and the operating charges. This subject is treated at some length in a series of papers.[8–11]

Aluminum-sheathed cables require corrosion protection if they are to be installed either in ducts, or to be buried underground, or to be carried aerially where unfavorable atmospheric conditions exist. The most desirable protection, as indicated in the foregoing, is black polyethylene and the recommended thicknesses of sheath and polyethylene are submitted in Table II. A typical economic comparison of lead-sheathed and aluminum-sheathed cables of equal ampacities will now be made. Each utility should make its own study using its specific conditions and should not draw too general conclusions from this example. The data are all given to three significant figures but the calculations were made with the necessary accuracy to give the final answer to that degree.

In this example, four sizes of 15-kv solid-type lead-sheathed cables of Association of Edison Illuminating Company dimensions with polyethylene jacket are considered and their ampacities determined by standard methods taking sheath losses into account. The same is done with the same sizes of aluminum-sheathed cables and ampacity curves are plotted against size for both types. By running across the curve sheet horizontally, the equivalent aluminum-sheathed cable sizes are obtained. These are as follows for three cables per duct bank:

Case	A	B	C	D
Amperes	251	330	397	482
Lead-sheathed, circular mils	212,000	350,000	500,000	750,000
Aluminum-sheathed, circular mils	220,000	380,000	575,000	over 1,000,000

These ampacities are for cables installed in ducts, three per duct bank, 75-per-cent daily load factor and are somewhat less than Insulated Power Cable Engineers Association values as sheath losses are estimated by the more accurate method cited here.

The next step is to estimate the d-c conductor losses which are as follows: Case *D* is dropped as 3-conductor cables of over 1,000,000 circular mils are not considered practical.

Case	A	B	C
Lead sheath, watts per foot	11.7	12.2	12.4
Aluminum sheath, watts per foot	11.3	11.3	10.8

The sheath losses are as follows:

		A	B	C
Lead sheath	$\frac{\text{Sheath loss}}{\text{Conductor loss}}$, watts per foot	0.00916 0.107	0.01950 0.238	0.0329 0.409
Aluminum sheath	$\frac{\text{Sheath loss}}{\text{Conductor loss}}$, watts per foot	0.048 0.542	0.104 1.17	0.185 2.00

The a-c losses, exclusive of sheath losses, are as follows:

Case	A	B	C
Lead sheath, watts per foot	11.7	12.6	13.2
Aluminum sheath, watts per foot	11.3	11.7	11.7

The total losses are as follows in kilowatts per 1,000 feet and annual kilowatt-hours per 1,000 feet assuming 50-per-cent loss factor:

Case	A	B	C
Lead sheath, kilowatts per 1,000 feet	11.8	12.8	13.6
Lead sheath, annual kilowatt-hours per 1,000 feet	51,800	56,200	59,600
Aluminum sheath, kilowatts per 1,000 feet	11.8	12.9	13.7
Aluminum sheath, annual kilowatt-hours per 1,000 feet	51,800	56,200	59,900

It will be noted that the total losses are substantially the same for lead-sheathed and aluminum-sheathed cables of equal ampacities. This simplifies the problem because the annual cost of the energy loss will be independent of the unit cost of energy and may, therefore, be neglected. The economic problem thus reduces to a comparison of the relative prices of installed lead or jacketed aluminum-sheathed cables, figures which will not be available until directly extruded aluminum-sheathed cables have become an economic reality.

Differences in cost of installation may be favorable to aluminum because of its lightness but, on the other hand, greater manhole costs may be involved with large cables as aluminum sheaths require a greater bending radius. Aerial cable fares better with aluminum sheaths, because, in most cases, the jacket may be omitted. An important field for aluminum-sheathed cables is likely to be gas or oil pressure cables of various types, as the great strength of aluminum enables higher pressure to be used than with plain lead sheaths and at a much lower cost than with reinforced lead. It is quite possible that cables of this type may eventually supersede several of the present-day varieties.[12-17]

Appendix. Burrell Method for Calculations of Sheath Losses

λ_s = ratio of open-circuit sheath loss to total d-c copper loss at 60 cycles

R_s = sheath resistance, microhms per foot

R_c = conductor resistance, microhms per foot

S = distance from conductor center to cable center, inches

C = mean radius of sheath, inches

d = diameter of conductor, inches

T = thickness of insulation, inches

$$\lambda_s = 3\frac{R_s}{R_c}\left[\left(\frac{S}{C}\right)^2\left(\frac{1}{1+0.00755R_s^2}\right)+\left(\frac{S}{C}\right)^4\left(\frac{1}{1+0.0303\,R_s^2}\right)\right]$$

$S = \frac{1}{\sqrt{3}}(d+2T)$ for round conductors

For sector conductors use 0.84 of equivalent d for round conductor.

Discussion

F. J. Aldridge and **P. A. Raine** (Johnson and Phillips, Ltd., London, England): We hope to be forgiven for writing from the other side of the Atlantic in a rather critical vein on the paper, but it seems to err by omission of much relevant matter. No mention is made of the fact that the paper only represents the experience of one company which, according to Table I, has only two commercially working installations of the cable. Neither does the paper attempt to confine itself to a full and detailed account of any particular aspect of the problem or to present new matter and we venture to suggest that most of the useful material in it has already appeared in one or other of our own many publications on the subject. It is perhaps unfortunate that the authors' European references do not mention either our pioneer work on the development from 1948 onwards, or the many thousands of miles of aluminum-sheathed cable we have in service.

Having made the point that one manufacturer's opinions only are presented, we examined some of them more carefully. In the section entitled "Sheath Manufacture" it is stated that "the hardness or stiffness of the sheath differs at a press stop." If by hardness the authors mean the value obtained by an impression instrument such as Vickers or Rockwell, we would disagree. If, however, they mean that the sheath is liable to fracture in that vicinity when bent, we would agree. This is not caused by hardness but by sudden transitions in grain size and shape. The only practical solution is to eliminate this suspect portion of the tube altogether, as has been our invariable practice, for we do not believe that any discriminating customer would knowingly accept cable on which a portion of the sheath was locally reinforced to protect an inherent weakness. As far as we are concerned there is no necessity to use tubes having stop marks since adequate lengths are available without them. Furthermore their elimination enables all other potentially dangerous parts of the extrusion cycle to be removed also. We feel that in accepting a tube containing billet joints, the authors are on dangerous ground, for the selection of tubes suitable for cable-sheathing involves considerably more than the mere imposition of pressure tests.

In the section entitled "Joining Aluminum Sheath," mechanical jointing is dismissed in a few words and welding is described as being in "about the same category." The authors discuss the comparative merits of helium and argon in the arc-welding process, but give no hint at all on the practical methods adopted to enable this high-temperature joint to be made on a cable without affecting the insulation. Now mechanical joints of one kind or another have been a familiar feature on aluminum-sheathed cables for many years, but a successful welded joint could represent a most desirable innovation. However, turning to Table I, we find that this type of joint has not yet been installed. If, as it appears, the method has not been tried in service then it should not be placed in the same category as the mechanical one already in general use.

This section concludes with a statement on the time-honoured method of the wiped joint, giving (with minor variations) details of the procedure first introduced by our company in 1948 and since adopted all over the world. A mechanical test for soldered joints is described which appears to be excellent, yet no test results are quoted to show that the particular tinning solder recommended is superior to any other. Could this have anything to do with the fact that Mr. Wyatt, in reference 15 of the paper, does not rate the corrosion resistance of this solder as any better than that of our 90-per-cent tin/10 per cent zinc? Incidentally, in reference 17, of the paper cadmium-zinc is recommended now admitted to be impracticable.

We note with interest that the authors could tin a tube satisfactorily with tin-zinc solder but were unable to achieve the same result when the tube contained a cable core. We cannot understand this for the many hundreds of cable jointers who have used our tinning solder here and overseas during the last 7 years have not encountered any similar difficulty.

Two further points on wiping are worthy of mention. The ladle or pot-wipe technique is not completely satisfactory for aluminum and we invariably recommend the

Table IV. Summary of Current Ratings for Aluminum-Sheathed Cables

In All Cases Equivalent Lead-Sheathed Cable Rating is 1.00

Type of Cable and Situation	Copper Conductors 0.10 Inches²	 0.50	 1.00	Aluminum Conductors* 0.10 Inches²	 0.50	 1.00
Single core (served) in air or buried	0.95	0.92	0.81	0.78	0.75	0.72
Single core (served) in ducts	1.20	1.01	0.95	0.92	0.84	0.84
Single core (sheath) bare in air	0.90	0.86	0.83	0.70	0.72	0.73
Three-core† (other than SA) served in all situations	1.00	1.00		0.78	0.80	
Three-core† (other than SA) sheath bare in air	0.96	0.98		0.75	0.78	

*The ratio of the d-c rating of a given size of aluminum conductor to that of a copper conductor of identical physical dimensions is 0.78.

†Factors relate to lead-sheathed and armored cable.

use of solder sticks to avoid it. Again the authors merely refer to "wiping solder (40/60)." Antimony is an undesirable element in such solder for use on aluminum, and either grades *40A* or *35A* of American Society for Testing Materials Specification *B.32-49*[1] should have been recommended.

In the section entitled "Corrosion Protection" the prominence given to differential oxygenation attack is commendable for it deserves wider publicity than it has hitherto received. However, the remainder of the section contains one or two surprises. The opening sentence states that protection against moisture is mandatory, yet Table I lists two aerial installations which are apparently to be erected bare. Second thoughts on this matter appear in the section entitled "Economics of Aluminum Sheaths," but the general treatment of corrosion is quite unhelpful for it gives no information to indicate where protection is necessary and where it is not required. Most surprisingly, the authors draw no attention to the fact that a wiped joint is more susceptible to corrosion than is the sheath itself and should always be protected as a matter of routine.

The section entitled "Economics of Aluminum Sheath," forecasts reductions in price when direct extrusion of sheaths is a practicable proposition, but otherwise confines itself almost entirely to the calculation of sheath losses. These calculations appear to obscure the real issue usually involved, namely, that replacement of a lead sheath by aluminum on large single-core cables materially reduces the current rating. We think that the position is shown better in Table IV, which summarizes British practice.[2]

Our only other criticism concerns Table II. We studied this Table when it appeared in reference 17 of the paper and to us it still remains an obscure and complicated method of tabulating sheath thicknesses. We would appreciate some information as to why this particular method of presentation was selected.

A. N. Arman (Pirelli-General Cable Works, Ltd., Eastleigh, Hants, England): Although the paper does not deal to any extent with the actual manufacture of aluminum-sheathed cables, it would seem desirable to mention a third method of manufacture, namely, the formation of sheath from rolled aluminum strip and welding the seam by means of a continuous argon-arc process. The presence of the seam may, at first sight, appear to be a disadvantage, because of the possibility of porosity or other defects. Manufacturing experience with the process has now reached such a stage in England that the continuous welding of sheaths is now being done commercially. As evidence of the quality obtainable, it may be mentioned that 23,000 yards of aluminum-sheathed 3-core 33-kv oil-filled cable has recently been satisfactorily completed using this method. When it is appreciated that this cable is finally heated in wet live steam and dried under vacuum within the sheath and that the smallest degree of porosity renders this process impossible, the high quality of the weld will be recognized.

Sheaths made by the strip-welding method have several advantages worthy of careful consideration. Strips can be joined (also by argon-arc welding) to enable sheaths of any desired length to be made. After being made, the strip joints require no special care in handling either in the forming machine or subsequently. The aluminum being rolled down (or corrugated if required) while still hot from the welding process is softer than that resulting from the cold drawing process and this gives better bending properties in the finished cable. The sheaths made in this way behave in exactly the same as those made by other processes, and I agree with the authors in most of the points they have mentioned regarding jointing, corrosion protection, etc.

The vulnerability of unprotected wiped splices and adjacent aluminum sheathing of trained duct cables as demonstrated in Table III is amply supported by experiments made in England. A more reassuring picture would have been presented if the investigation had included corrugated sheaths with wipes protected with bitumen.

The losses discussed are interesting but, I think it should be made clear that in the case of single-core cables (with fully bonded sheaths), the losses are usually considerably higher for aluminum-sheathed cables than for lead-sheathed cables. I disagree with the authors statement that the ultimate aim is continuous and direct extrusion from press onto cable core. This may be true if an extruded tube is considered to be the only sound method of approach. Experience in England is showing, however, that the welded-strip method is entirely feasible and has many advantages. Not the least of these are that the cost of the plant is only about one tenth of that required for extrusion and that sheath eccentricity (which can also be a costly item) is nonexistent.

C. C. Barnes (British Electricity Authority, London, England): This paper is of particular interest at the present time because of the persistent high-price level and steadily increasing cost of copper which tends to make the use of other metals very desirable, particularly if their use is technically feasible and they offer an economic advantage. Considerable use has been made in Europe of both aluminum conductor and aluminum-sheathed cables.

In particular, in Great Britain aluminum-sheathed cables have been widely used as an alternative to the lead-cased cable—the total length manufactured to date is in excess of 3,500 miles while, according to K. S. Wyatt, a total of perhaps 500 miles has been made in Germany.

British Standard *480-1942*[1] was revised and reissued in 1954 in two parts. Part II at the present time is confined to aluminum sheaths applied by the tube-sinking process; other techniques, however, are used in Great Britain, such as the longitudinal welding of strip formed into aluminum tube developed by the Pirelli-General Cable Works and the Research Laboratories of the General Electric Company (England) and a hot extrusion process, but this latter technique has not yet been fully developed on a commercial basis. I note with some regret that the authors have omitted to make any reference to the pioneering work of P. M. Hollingsworth and his associates who in 1947 were responsible for the first commercially successful technique for applying an aluminum sheath by the tube-sinking process.[3]

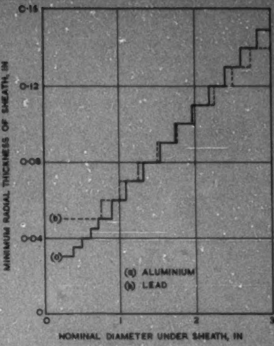

Fig. 14. Sheath thickness in relation to cable sheath diameter

Tests in Great Britain have established that bending performance alone decides the gauge of an aluminum sheath. Fig. 14 shows a sheath thickness for aluminum-sheathed cables and lead-sheathed mains cables standardized to British Standard *480-1954*. The importance of a high-grade corrosion protection for aluminum-sheathed cables cannot be overemphasized. Mr. Del Mar and Mr. Merrell make a very definite recommendation to use an extruded polyethylene jacket but, unfortunately, they do not give any test data to justify this observation.

In Great Britain the standard procedure for assessing the performance of protective coverings consists of measuring leakage currents passed by the servings on short samples of cables continuously immersed in a tank of electrolyte (usually 0.5-per-cent sodium chloride). Prior to the test the samples are subjected to a bending test and retain the final bend when placed in the tank. The electrolyte is heated daily and observations of leakage current are made at the highest and lowest temperatures, the sheath being maintained at a constant voltage of −10 volts with respect to the electrolyte. The criterion of quality is the absence of any tendency to increased leakage current, irrespective of the duration of the test. In some cases the bent sample has been supported on brick in the tank to check the mechanical ability of the covering to withstand contact with bricks or flints which may inadvertently have fallen into or been left in the cable trench.

I would welcome details of long-time tests the authors have made to assess the immunity of an extruded polyethylene sheath to aging attack by any type of soil, duct material, or any other condition likely to be encountered in the ground. Furthermore, the authors' views on the technical and economic merits of neoprene jackets for aluminum-sheathed cables will be appreciated.

The life of all buried aluminum-sheathed cables is unquestionably dependent on the perfection of the jacketing materials. In Great Britain all lead-sheathed oil-filled and/or gas-pressure lead-sheathed cables have a metallic reinforcement and, therefore, aluminum as a cable sheath is particularly advantageous when the mechanical properties of the sheathing material have to withstand internal pressure, and increasing use is being made of such cables in Europe.

Philip J. Croft (Canada Wire and Cable Company, Ltd., Toronto, Ont., Canada): The position and experience of my company has already been fully dealt with by Mr. Short and Mr. Kozak in their excellent discussion. However, there is a point in connection with bending radii and flexibility of this type of cable which is worth mentioning. In our draw-down method of manufacture, the aluminum tube, as we receive it from the extrusion press, is in a range of fixed steps as to diameter and wall thickness. The cable cores which may have to be sheathed, however, may vary infinitely in diameter, or at least in steps of a few mils.

The diameter of tube chosen for the sheathing of any particular core is limited on the lower side by our ability to draw the core smoothly and safely into the tube and, on the upper side, by the amount of cold-working considered prudent to do in the drawing-down operation. A number of standard factory procedures have been tabulated, but it is obvious that a core of the maximum diameter for a certain size of tube will receive the minimum amount of drawing down and consequent cold-working, whereas a core of a few mils larger could, according to standard-tabulated procedures, be sheathed from the next larger tube and thus receive practically the maximum amount of drawing down and consequent cold-working.

As a result of this, it has become our practice to exercise some engineering discrimination in the selection of a tube size for sheathing depending upon the end use to which the cable is to be put. For example, if the cable is intended for surface-supported power circuits in a factory or similar application in which the cable sheath to some extent takes the place of a conduit, we would permit a relatively larger amount of drawing down, since a little extra stiffness in the cable sheath enables the cable to be supported at wider intervals approximately equal to those used in supporting conduit, with consequent economy in the over-all cost of the job, while bends are usually no problem in this kind of application. For duct and manhole use, we would take steps to sheath the cable from the smallest aluminum tube into which the core could safely be drawn to minimize the amount of cold-working and preserve, as far as possible, the original ductility of the hot extruded tube. The industrial surface use of this material represents a very considerable proportion of our output, and it does seem to me that the intended end use of the cable has a large bearing upon the need for flexibility in the cable.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): In recent years, a sharp increase in the interest in and use of aluminum as sheathing of cables has occurred in Europe and this country. This applies to certain types of installation in each of several fields of cable use. In the power-utility field in Europe, I found last fall that not only had much been done but that pioneering activity was increasing, especially since three different designs of presses to extrude aluminum sheaths directly onto cable cores were being developed. In Canada, much has been done on drawn-down sheaths on a variety of cables.

The authors have presented extensive and valuable data regarding drawn-down aluminum sheaths. In so doing, it seems to me that for some applications they have emphasized the advantages and need for extruded sheaths. Such sheaths are more ductile than drawn-down aluminum sheaths, as the elongations of the extruded sheaths in tensile tests may be three or four times as much as for drawn-down sheaths. Furthermore, it will not be necessary to use the expensive aluminum of 99.99-per-cent purity to obtain these high elongations. Incidentally, the tensile strengths of such extruded sheaths may be about one-half of that for drawn-down sheaths.

With the extruded sheaths, it appears that the thicknesses may be reduced appreciably below what the authors show in Table II, partly because there will be a reduced tendency to corrugate. With thinner sheaths, the magnitude of sheath losses in 3-conductor cables will be reduced. With extruded sheaths, the training radius for the larger cables may be much less than the 15 to 25 times the cable diameter, which the authors mention. For lead-covered cables we generally use a training diameter of eight or nine times the cable diameter. The extrusion process will make feasible the manufacture of extra long lengths. Perhaps, with the extruded sheath, the amount of voids intentionally left in solid-type cables may be reduced below what the authors describe with drawn-down sheaths.

It is appreciated that the installation of an extrusion press is very costly, and so discussions and technical and commercial studies are necessary to determine how many such presses need be installed after satisfactory presses have been developed. The European presses being developed will result in sheaths having press stops incidental to recharging. Limited information and observations on sheaths extruded by one type were encouraging as to the mechanical properties of the press-stop region of the sheath.

The results of the bend tests given in Table III are somewhat discouraging. With a sheath strain of 0.27 per cent, and a splice on the cable in three different tests, the cycles to fracture at room temperature ranged from a title to greatly less than are obtained with arsenical and tellurium-bearing alloy lead sheaths even when heated to 43 C. The authors' opinion on the cycles to fracture with extruded aluminum sheath would be of interest.

I believe that in economic studies of particularly the losses in aluminum sheaths of 3-conductor cables the cost of equipment to supply the losses should be taken into account. If there were no losses in a transmission and distribution system of a utility, then it would install 10 to 15 per cent less generating equipment and less facilities outside the stations.

C. T. Hatcher (Consolidated Edison Company of New York, Inc., New York, N.Y.): To obtain operating experience with the use of aluminum sheath cable, an installation of approximately 5,000 circuit feet of single-conductor 2/0 paper-insulated aluminum sheath, polyethylene jacket 27,000-volt triplexed cable was made during February 1954. This cable was installed instead of 3-conductor 2/0 standard lead-covered cable in the Bay Ridge section of Brooklyn along 72nd Street, between Fourth Avenue and Shore Road. This cable was energized on April 8, 1954.

This cable was installed using a special pulling compound known as Bentonite and was racked in the manholes with a minimum bending radius of 15 times the maximum outside diameter of the cable. The joints were made using the standard lead sleeve with the aluminum sheath tinned with a special solder consisting of 77-per-cent tin, 20.5-per-cent zinc, and 2.5-per-cent lead. The sleeves were wiped using standard 40-per-cent tin, 60-per-cent lead solder, with the solder temperature maintained at approximately 550 degrees Fahrenheit. After the wipes were completed and tested, the tightness at 15 pounds per square inch, the lead sleeve, wipes, and the adjacent exposed aluminum sheath were covered with a minimum of two layers, half-lapped, of 2-inch polyvinyl chloride tape. The polyethylene jacket was removed for approximately 6 inches at the point where the bonding cable and test strips were installed. The aluminum sheath was tinned with the special tinning solder described in the foregoing. The bonding cable and test strips were then attached using standard wiping solder and two layers, half-lapped, of 2-inch polyvinyl chloride tape was applied.

On December 2, 1954, an inspection was made to determine the condition of the aluminum sheath and solder wipes at a joint and bonding connection in one of the manholes. This manhole was selected for inspection because the joints had been exposed to submersion at times. The aluminum sheath, solder wipes, and lead sleeves at the joint and at the bonding point showed no signs of corrosion. There was no apparent evidence of interfacial corrosion between the aluminum and solder wipes. The joint and the bonding connection were retaped with polyvinyl chloride tape, with a coat of Roybond *A-36* metal primer before the application of the tape.

P. M. Hollingsworth (British Insulated Callender's Cables, Ltd., London, England): The comprehensive survey of aluminum-sheath characteristics and recommendations for jointing technique, corrosion protection, and the like seems at first glance rather ambitious when judged on the basis of Table I which lists the installations to date. Reference to Table I shows that of the four items mentioned, totalling 32,000 feet, only two had been installed when the paper was written, one length (unspecified) in ducts and one length (also unspecified) in air. Both of these carry a protective covering of extruded polyethylene on the sheath, but the later installations carry no such covering. It seems, therefore, that considerable undisclosed laboratory work must have been done or else much of the information has come from experience with aluminum-sheathed communication cables.

In general the data given and the opinions formed are in satisfactory agreement with conclusions that have been reached from experience in Great Britain and elsewhere derived from manufacture and installation of several thousand miles of cable which began in 1947. The great bulk of this production which covers a voltage range up to 33 kv including impregnated pressure-type cable has been sheathed by the died-down process and this type of cable is now covered by British Standard *480*, part II. There is also now a method operated in England employing strip folded round the cable cone and welded longitudinally. Finally, the direct extrusion method is being actively developed by my company.

I find myself somewhat at variance with the authors on the subject of jointing technique. In the first place, tin-zinc solder decried by the authors has been used on many thousands of joints as well as in hundreds of tests and has given every satisfaction. It certainly by no means requires such careful handling as that indicated by the rather elaborate procedure described for the tin-zinc-lead combination favored by the authors. An alternative which has been found similarly satisfactory and even easier to work is a tin-zinc-cadmium alloy.

I can confirm the excellent mechanical properties of cadmium-zinc solders and also the scorching of the insulation which prohibits their use. In that connection, the reference in the paper to the use of argon arc-welding is very puzzling since the temperatures involved must be completely destructive to the insulation unless some highly specialized procedure has been evolved. Perhaps the authors would enlarge on this point.

Statements relating to the need for protective coverings on wiped joints and sheaths seem rather contradictory as follows: "Protection of wipes and sheaths from moisture . . . is mandatory" and "Aerial cable . . in most cases the jacket may be omitted." I agree that it is essential to protect wipes and soldered joints from contact with water under conditions of immersion, but have yet to meet any case of corrosion in a wiped or soldered joint installed in normal atmospheres, rural or industrial, whether humid or otherwise. The use of extruded polyethylene for corrosion protection where this is required is to be commended and the reduction in thickness of the aluminum sheath when furnished with a polyethylene jacket is an interesting innovation.

On the subject of economics, the authors illustrate the effect of sheath losses on current ratings of 3-core cables. This effect is not noticeable on 3-core cables under British practice since, for conditions of direct laying, current densities are higher and the basis of comparison for sheath losses is between lead-sheathed and armored finish on the one hand and aluminum on the other. The same conductor sizes would therefore be used in Britain for both lead-sheathed and armored and aluminum-sheathed cables for the four ratings given in the paper. For 10-kv screened-type cables these would be 251, 330, 397, and 482 amperes for 191,000, 318,000, 446,000, and 637,000 circular mils respectively. The bases of computation for the foregoing are: Single circuit laid direct, 100-per-cent load factor; thermal resistivity of soil, 120 thermal ohms per centimeter cubed; soil temperature, 15 C, and conductor temperature, 65 C.

Under these conditions the total losses would show only very slightly to the disadvantage of the aluminum-sheathed cable. Much more significant is the increase in losses when single-core cables are employed with bonded sheaths which cause substantial reduction in ratings for conductor sizes above 400,000 circular mils.

S. J. Rosch (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): The authors have made a particular point of the fact that most installations of aluminum-sheathed cables of record are of the aerial or of the indoor type but that the present paper is directed not only to these but also to aluminum-sheathed power cables intended for installation in underground ducts. It is therefore regrettable that this excellent paper does not contain any data on creep resistance of such types of cable.

Aluminum-sheathed cables are being considered as a substitute for corresponding lead-sheathed types. The literature is replete with data regarding studies of creep resistance of the latter types and, in order that a full realization may be had of the comparable behavior during load cycling in modern manholes, similar data on aluminum-sheathed power cables are highly essential. It is possible that the authors have such data as a result of the studies conducted in their laboratory and it would be appreciated if some of these data were given.

H. D. Short and **S. Kozak** (Canada Wire and Cable Company, Ltd., Toronto, Ont., Canada): The authors are to be complimented on their paper and its contributions to the furtherance of aluminum-sheathed cables. Unfortunately they neglect to mention the achievement of the firm of Johnson and Phillips, Ltd. This firm in 1948 achieved on a feasible scale the only presently commercial means of applying seamless aluminum sheath[1] to all types of insulated wires and cables. It is their development which has excited and redoubled the efforts to hasten the application of aluminum to sheathing cables. If the authors' 2 years of experience and 32,000 feet of cable installed are termed considerable, then we would say that the experience and production of Johnson and Phillips, Ltd., in England and Canada Wire and Cable Company, Ltd., in Canada can be termed astronomical.

The background of our company in production and application of aluminum to power cable sheaths extends to over 2,500,000 feet of aluminum-sheathed cables of all types including the following specific projects:

1. 57,000 conductor feet 69-kv type SA gas-pressurized cable—duct bank installation in Vancouver, B. C.

2. 25,000 conductor feet, 120-kv oil-filled cable—duct bank installation in Montreal, Que.

3. 6,300 conductor feet 301-kv oil-filled cable—tunnel installation at Kemano, B. C.

4. 1,000 conductor feet 161-kv gas-pressurized cable, direct bury, terminating ends for pipe-type cable—Toronto, Ont.

With this experience we have maintained practices which are at variance with those adopted or proposed by the authors. It has not been considered necessary to vacuum-treat or dry-gas charge the tubing after extrusion. One would expect that during draw in any benefits of vacuum treatment would be lost. We stipulate pressure tests to detect pinholes and other defects but do not pressurize the tubing during shipment or storage. We definitely do not accept lengths of tube with press stops or billet joins, believing as the authors assert that these defects remain as significant factors. Until more knowledge is accumulated on all the ramifications of press stops and billet joins, which we have found unsatisfactory on bend tests, we would prefer not to supply aluminum sheath with these imperfections remaining. The practice described by the authors of temporarily reinforcing press stops would seem to be a shortsighted and dangerous practice, not worthy of the excellent and uniform properties obtainable from continuous tubing. This type of patching would not be tolerated on lead-sheathed cables, and if only in fairness to aluminum-sheathed cables should not be permitted. Our purchase specifications prohibit press stops and billet joins, stipulate scrupulous visual, tensile, elongation, and physical tests, and permit no dents, corrugations, eccentricity flattening, scores, or gouges.

We view with suspicion the authors' claim that an extruded polyethylene covering would permit material reduction in wall thickness for the following reasons: the process of factory handling before extruding the polyethylene sheath would produce the corrugations prior to whatever advantage could be realized, unless, of course, abnormally large reels are used in the manufacturing processes; and because bending in the field could produce corrugations underneath the polyethylene which might subsequently prove damaging to the covering.

We are somewhat surprised but nevertheless very interested in the authors' claim that welding is the most effective means of making joints, particularly for paper cable. The question immediately arises as to what clearance the authors find necessary to allow for expansion of core and impregnant under the fusing heats required. We would also ask if the authors have encountered any bursting of the sheath, or bubbling of the impregnant through the molten weld metal and resulting porosity. We suspect that the authors have retreated to the welding alternate because they have not arrived at the proper method of applying the tin-zinc wiping technique. This is in evidence from the method described in the section entitled "Jointing Aluminum Sheath." One can have defective welds in the field more readily than defective wipes, especially with aluminum and, unless the welders are most expert in handling aluminum and aluminum alloys in welding aluminum it is most important to have full knowledge of the alloys and metals being jointed. It does not seem too practical to have to rely on expert welders in the field; it is much better and easier to train cable splicers in the proper technique of wiping on to aluminum.

We note the authors' assertion, in contradiction to a previous claim by their company (ref. 17 of the paper) of the unsuitability of cadmium-zinc tinning solders caused by the high temperatures necessary, but we cannot understand the authors' experience with tin-zinc solders as effective on tube and sheet, but ineffective on sheaths, although it is no doubt related to the tinning techniques employed by them.

We suspect that some foreign materials are introduced in the swaging-down, or subsequent handling processes which are not properly removed during the attempts at tinning. Are the same results obtained on sheet, tube, and sheath with the cadmium-zinc alloys? The tinning procedure should include two important steps which are not described by the authors: first, the sheath should be cleaned of any oil film, using appropriate nonresidue-forming solvents; secondly, the friction tinning should be immediately followed by vigorous rubbing of the molten tinning metal, using a stiff wire brush. This tends to break down the oxide film and flows the tinning metal into intimate bond with virgin metal. We are amazed to notice that the authors have failed to appreciate the importance of wire-brushing the tinning metal—this is the whole crux of successful wipes on to aluminum sheaths. Heat during tinning accelerates formation of the oxide film and it is essential that the tinning metal "marries" the aluminum metal and not the oxide film. This can only be ensured by the proper brushing while the tinning metal is molten. Stick wiping is preferred to pot wiping of the wiping metal. We always use a small amount of acid-free flux on the wiping cloth, taking care not to allow the cloth to come in contact with the tinned surface.

If the techniques of tinning and wiping, as we have outlined them, are followed using 90/10 tin-zinc tinning metal, aluminum sheaths can be sealed at junctures such that under any normal duty in service the wipes will perform most satisfactorily.[1]

In respect to bending tests, and contrary to the experience and opinions of the authors, our experience on similar tests using similar equipment on sheaths and tubing with copper sleeve joints and tin-zinc tinning have shown that the design of joints for duct bank and manhole applications of aluminum sheath, under Canadian and American conditions, is well beyond the development stage. In point of fact, backed by several years experience on 69-kv and 120-kv installations, joints in such applications of aluminum sheath are no more a problem than for installations of lead-sheathed cables. Employing a 48-inch-long 5-inch-diameter copper sleeve joint, $2^1/_4$-inch-diameter cable specimens, and the tinning and wiping technique just described, our laboratory bend tests have followed closely that revealed by the authors in Fig. 10. Fig. 15 illustrates in general the test arrangement we used which shows the cable trained as would be the practice for a lead-sheathed cable in a 14-foot by 9-foot manhole. Tests of this nature have been conducted introducing such variables as continuously wet wipes, duct cable movements as high as 1 inch, free and restrained lateral movement of the joint, and internal pressures as high as 25 pounds per square inch gauge. In contradistinction to the authors' experience, our test specimens under 25 pounds per square inch pressure above atmospheric have never developed wipe or sheath failures after as many as 630,000 cycles at speeds as high as 55 cycles per minute and a cable longitudinal movement of 1 inch. At the 630,000th cycle the test was stopped as it appeared that the specimen would continue under this movement for many more cycles without failure and, the 630,000 cycles represented many times the 50-year life expectancy.

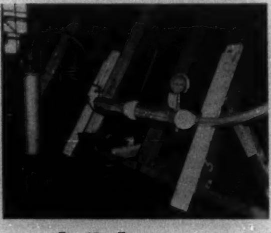

Fig. 15. Test arrangement

These test results are so at variance with those reported in the paper that we not only suspect the tinning and wiping techniques employed by the authors but also the grade of aluminum tubing metal. Could the authors state whether or not their aluminum sheathing is of the same grade as that reported in reference 2? In addition to what we have said about welded joints, we noted that Table III does not present any stronger case for the welded splice as for their type of wiped splice. It would appear that their welding method weakens the sheath metal seriously even at the internal pressure of 5 pounds per square inch gauge which they used.

In the section entitled "Solid-Type Paper Cable" the authors state that such cables may not have ionization factors as good as virgin lead-sheathed cables. Are they giving their opinion based upon their own theories or upon actual tests?

Our installation experience has not revealed any need for braking the reel to straighten the cable; our experience includes the pulling of the 301-kv all-aluminum cable.[3] Mr. Del Mar and Mr. Merrell's suggested box straightener might prove useful, but we would expect that the first few feet of a duct would achieve the same results. We confirm[1] their recommended manhole training radii of 12 to 15 times the cable diameter although we have never found it necessary to resort to special bending tools for training, except for very large cables having unusually thick sheaths. Normally the same methods as employed for lead-sheathed cables suffice for manhole training.

We share the authors' opinions in regard to corrosion protection for aluminum-sheathed cables and the dissimilar metal juncture at the wipes[1] and we have invariably used a protective coating over the wipes. However, for duct bank installations, we feel that caution should be exercised if polyethylene covering is used over the cable per se. The solvent effects of petrolatum compounds on polyethylene is well known and we would view with concern the use of such a covering in ducts into which cable has been previously installed because of the possibility of remnant quantities of unknown pulling-in greases. We should for the general case much prefer the type of covering used for the cables reported in reference 1, this being our standard practice for high-voltage cables of all designs.

Figure 11 shows a pulling eye and solder seal on an aluminum-sheathed cable. We have not found it necessary to make use of pulling eyes with aluminum-sheathed cables, our normal practice being to pull directly on the sheath or over the rubber sandwich protective covering by means of Kellem grips. They work admirably and avoid the necessity of special pulling-eye devices.

W. A. Del Mar and **E. J. Merrell:** We are very grateful for the excellent discussions of our paper, especially by our British and Canadian friends who have had experience with aluminum sheaths. Several discussers have deplored the absence of acknowledgement to prior workers in this field. We have purposely avoided historical references as it is very difficult to assign precedence especially where, as in this case, parallel work has been carried out in several countries. One historical reference in the beginning of the paper was mentioned to show the long lag between the first appearance of aluminum on a commercial scale and the present activity on cable sheaths.

Mr. Aldridge and Mr. Raine speak from the experience of a company which has done more than any other in English-speaking countries to develop and further the use of aluminum-sheathed power cables in those countries. They should not, however, forget the very extensive pioneer work by the Germans, especially Messrs. Felten and Guilleaume. Indeed, the German experience with aluminum-sheathed cables goes far beyond the British, and our work stems from the German much more than from the British experience.

As licencees of Felten and Guilleaume for communication cables of the type known as styroflex and as makers of another type known as spirafil, the experience of our company covers over 2,000,000 feet of aluminum-sheathed cables of diameters from 3/4 inch to $3^1/_4$ inches. Our paper, therefore, does not "represent the experience of one company which. . . has only two commercially working installations of the cable," but has a very extensive background of experience.

The purpose of the work covered by our paper was to adapt this experience with communication cables to American practice with power cables, both for installation in ducts and as supported on poles by messenger cables, neither of which subjects is covered by British publications.

The very extensive British use of aluminum-sheathed cables indoors cannot yet be duplicated in the United States because of a prohibition by the National Electrical Code, and buried cables, except for street lighting, are not used.

The statement that sheaths show no change of hardness at press stops as measured by a Rockwell instrument is, in our opinion, not strictly correct. We have found a very considerable variation of Rockwell penetration along an aluminum sheath which tends to mask any specific change at the press stop. However, looking over a large number of readings, we find a general trend toward a less penetration, in the Rockwell test, at the press stop. An example of such a case, using the Rockwell L scale and a 1/4-inch ball, showed a change from an average of 59 to 67 at the stop. In no case did we find the reverse.

The reason why we do not exclude press and billet stops from our regular production is given in our reply to the discussion by Mr. Short and Mr. Kozak. It is a purely economic question based on relative labor costs in our respective countries. The reason for the omission of details on arc welding is also given below in our reply to Mr. Short and Mr. Kozak. Suffice to say, for the present, that we flare the sheath before welding.

Our laboratory tests of mechanical joints made on our manhole bending machine, since the present paper was written, have given excellent results. While the British and Germans have made mechanical joints, we do not know whether these will stand up in such a test.

We are told that no results of our screening test are given to show which particular tinning solder is recommended as the best. That was not the purpose of the test. As stated in the paper, the purpose was to identify the less promising mixtures. After eliminating these, practical tests of the remainder determined our recommendations.

We saw the tin-zinc solder in use at the Johnson and Phillips Works in 1952 and could see no difference between their procedure and ours. The difference in our evaluation of this solder must arise either from differences in materials or from our respective views of what is good and what is bad. We are inclined to believe that it is the latter. It should be remembered that our severe manhole bending tests eliminate many joints that seem excellent by all other tests. When this test is used on large cables, there is a tendency for the cable to move from the manhole toward the joint without much bending. This puts a very severe shearing stress on the wipe of the joint and wipes which pass every other kind of test may fail grievously in this one. This is the ultimate test which a wiped joint or, indeed, any kind of joint must withstand in American practice.

The section entitled "Corrosion Protection" says that protection against sources of corrosion is mandatory. Where these sources do not exist, such protection obviously is not necessary. It is required for all duct cables and for aerial cables when installed either in a salty atmosphere near the sea or near industrial plants which may emit corrosive fumes. Under other conditions we believe that protection may not be required. The same is true of most indoor installations. Mr. Aldrich and Mr. Raine are surprised that we draw no attention to the fact that a wiped joint is more susceptible to corrosion than the sheath itself. They seem to have missed the point of our ring test which is entirely based on that assumption.

The reference to single-conductor cables with fully bonded sheaths has little or no application in United States practice, as no one here would ever bond the sheaths of single-conductor cables under conditions where the sheath losses would be appreciable. The procedures used here are described by H. Halperin.[1] Table II is based on our experience with avoidance of buckling of the sheath when bent to suitable reel radii.

Mr. Arman's description of the strip welding process is very interesting and indirectly affords us some support for our advocacy of welded joints. His comment on single-conductor cables has been answered in the foregoing.

Mr. Barnes asks for reasons for recommending a polyethylene jacket. Our tests on such jackets were completed many years ago, but our main justification is the successful use of well over 1,000,000 feet of lead-sheathed polyethylene-jacketed cables in ducts. American polyethylene does not contain polyisobutene which may explain the difference in experience in the two countries. Greases containing soap, however, should be avoided.

Mr. Barnes regrets that we have not referred to the work of P. M. Hollingsworth and his associates. If our paper had been historical, we would not only have done that but would have referred to the pioneer work in other countries, especially Germany.

Mr. Croft's discussion relates to an important precaution which should be taken in selecting tubing for draw down, with which we fully agree.

Mr. Halperin calls attention to the difference in hardness of sheaths made by the draw-down and direct-extrusion press methods. Until more experience is available with the latter, we think it safer to draw no conclusions, especially with relation to manhole life. Certainly the direct-extrusion method gives a softer and more ductile sheath which has both advantages and disadvantages.

Mr. Hatcher's experience which relates to the first item in Table I, is very valuable. We hope to have more of this kind in the near future.

Mr. Hollingsworth, who is one of the recognized pioneers in this work, is right in saying that our survey seems, at first glance, to be rather ambitious if based on the limited experience with the cables listed in Table I. He is quite correct in assuming that considerable undisclosed laboratory work and field work as well came from our experience with communication cables and, we should add, with polyethylene-jacketed lead-sheathed cables.

The tin-zinc solder which Mr. Hollingsworth has found satisfactory will not meet the conditions of American service, because cables in manholes are operated at higher temperatures than in European countries.

No trouble has been experienced with scorched insulation when using argon welding in the laboratory. A field installation using this procedure is about to be made and may lead to modifications of the laboratory procedure. We therefore postpone giving details of our procedure until it has had a practical trial.

We have answered the point about protection of wipes and sheaths from moisture and the apparent inconsistency of having an unprotected aerial cable.

Mr. Hollingsworth's data on the relative sizes of aluminum- and of lead-sheathed cables in British practice are very interesting and may be one of several reasons why aluminum sheaths have been more attractive for power cables in Britain than in America.

Mr. Rosch asked about the creep characteristics of aluminum sheaths. We have done very little work on this and refer him to the excellent paper by P. M. Hollingsworth and P. A. Raine.[2]

Mr. Short and Mr. Kozak have given an interesting outline of their company's experience with aluminum-sheathed cables, and their confidence in these is additional positive evidence of the applicability of this material for cable sheathing. Their gross footage is virtually identical with our 2,000,000 plus figure. However, whereas our shipments have been almost completely in standard 1,000-foot lengths, theirs apparently have been confined for the most part to very much shorter sections for the larger diameters because of their restriction to lengths of tubing from single billets or blooms. In this connection, while our total footage of power cable is only a fraction of our product to date, it is noteworthy that each application is purposely distinctively different in many pertinent respects. These features merit consideration where space will permit a more complete analysis of important points. Also, we can report that our applications of other types of aluminum-sheathed cables include numerous installations in a variety of environments, buried, plowed-in, submarine, and the like.

Our vacuum treatment assures the absence of moisture, a very practical consideration in respect to paper cable. The temporary reinforcement of press stops is not a patch. It is a sound precautionary procedure. It would seem the discussers have chosen to forego employment of any of the new semicontinuous ram-type aluminum extrusion presses. Would they rather confine aluminum-sheathed power-cable applications to short manhole lengths with the requisite superabundance of joints, the latter certainly just as doubtful as press stops? This is completely counter to the trend in the United States because of the high labor cost of joints.

Our purchase specifications for aluminum tube necessarily are very rigid to enable precision production of styroflex coaxial cable where dimensional control is by mils.

Mr. Short and Mr. Kozak's surmise that we use abnormally large reels on all factory operations is correct, so that the possibility of corrugations is not a manufacturing problem. Our background of field experience with polyethylene-jacketed lead-sheathed cable now has been supplemented by approximately 100,000 feet of aluminum-sheathed cable so protected, with no instability indicated to date, nor do we anticipate any.

We consider welding to be the most permanent moisture seal, all things considered

Far from retreating, but recognizing the applicability of all classes of seals, all have been under development simultaneously without prejudice. Welding aluminum admittedly requires a high skill, but a few practical precautions and intelligent design of accessories seem to suffice to make the operation feasible. Oil and other contamination cannot be tolerated. The presence of any contamination indicates itself immediately in a discolored and porous weld surface, and in this way welding is self-monitoring. We can offer the assurance that our current techniques do not result in excessive heating of the cable core as indicated by multiple thermocouples.

Unsatisfactory experience with 90/10 solder is not unique with us. Nor have we neglected to employ any of the pertinent preparatory procedures mentioned. The discussers appear to have missed reading point one of our tinning procedure, namely, "Make certain the sheath is free of oil film and like contamination. Stearine is not to be used on the aluminum."

It is difficult for us to make a comparative evaluation of the 630,000-bend-cycle figure, since so many significant factors are not given by the discussers, e.g., the maximum sheath strain, the offset, and the training radius (which from Fig. 15 appear much greater than in our tests), and sheath thickness. Instrumentation pressures, whether 5 or 25 pounds per square inch have no bearing on bend life. However, bending rates in excess of 1 cycle per minute seriously reduce the proportionate effect of stress corrosion on bend life and, therefore, are not realistic. In our opinion, a rate of 55 cycles per minute is entirely too fast.

Ionization factors are influenced by cable type, whether belted, shielded, time of storage, range of ambient during storage, etc. In some instances, tests have shown higher ionization factors for aluminum-sheathed cable samples than we have become accustomed to expect for their counterparts with lead sheaths. We do not attach any significance to this characteristic, as indicated in our paper, but mentioned it for its academic interest.

We, too, have not found the straightening block or braking necessary for duct work. These measures are desirable for those aerial applications where the best possible appearance is sought.

The discussers in referring to the solvent effects of petrolatum on polyethylene must have in mind the characteristics of polyisobutylene blends of polyethylene or low molecular weight types made in England during the war. Pure high molecular weight American grades of polyethylene exhibit outstanding stability in oils at cable sheath or jacket operating temperatures.

A Simplified Method of Calculating Voltage Regulation Using Unit Impedance Power-Reactive Diagrams

R. M. BUTLER
MEMBER AIEE

Synopsis: The methods of analysis described provide a convenient way to calculate the voltage regulation characteristics of a transmission network as viewed from a single bulk load connected to the network. The methods apply equally well for single transmission lines and radial type of multiple circuit systems.

THE modern accepted practice for studying voltage, power, and reactive flow conditions on a transmission and subtransmission network is by use of such analytical tools as the a-c network analyzer. However, this valuable calculating aid is generally used for major system studies dealing with alternative plans for future expansion and is not always available when needed for problems of smaller scope such as determining the voltage regulation characteristics of the network as viewed from one substation. Occasionally, it is desirable to know what effect increased load or power-factor correction in the underlying distribution system will have on the voltage at a substation feeding the underlying system.

The methods discussed in the paper offer a convenient way of studying such voltage regulation problems primarily by manual calculation. If the supply system is a complex network, two simple measurements can be made when the network is set up on an a-c network analyzer for other studies. These two measurements are the open-circuit voltage E_{OC} and the short-circuit current I_{SC} at the point of interest on the network. Since steady-state voltage regulation problems are described, it is not necessary to insert the generator transient reactances into the network when measuring I_{SC}. Hence, this value of current is not the short-circuit current usually obtained in fault studies.

Using the values for E_{OC} and I_{SC}, the remaining calculations are performed manually. The advantage in using the methods described is that very little mathematical computation is required since a unique form of power-reactive circle diagram is used to give graphical solutions to the voltage regulation problems.

Summary of Method

The steps necessary in determining the voltage regulation characteristics at a load point on a power network are briefly as follows:

1. Obtain the open-circuit voltage E_{OC} at the load point in question with the load removed.

2. Obtain the impedance of the network Z_D as viewed from the load; this is the driving point impedance of the network measured at the load point.

3. Let the impedance Z_D be the equivalent impedance of the network and the voltage E_{OC} be the input or sending end voltage of the equivalent impedance.

4. Let the voltage E_{OC} and impedance Z_D be the base voltage and base ohms of the equivalent system respectively so that E_{OC} and Z_D can be expressed as 1.0 per-unit (pu) quantities. Then calculate the base kilovolt-amperes (kva) so that load power and reactive may also be expressed in pu on the calculated base kva.

5. Determine the load voltage E_2 for any value of pu power and reactive load using power-reactive circle diagrams for a unit impedance-unit input voltage circuit. E_2 will be measured on the power-reactive diagrams in pu of the sending voltage E_{OC}.

The first two steps listed for determining E_{OC} and Z_D can be performed manually if the supply system to the load is a transmission line or a radial-type supply system. Use of the network analyzer will be preferred to measure

Assumptions

The method used in calculating the voltage at a particular point on a network for various load conditions at that point is based upon two assumptions:

1. Changes in the steady-state load at a given point in a network will not cause a change in generator bus voltages.
2. Loads connected to the supply system network feeding a particular load of interest are assumed to have constant impedance characteristics. Changes in load at the particular point of interest will cause some variation in the voltage applied to the other loads connected to the supply system. However, it is assumed that these voltage variations will not be of sufficient magnitude to cause serious error in computation if the loads, other than the one of interest, do not have constant-impedance characteristics.

Discussion

Step 1—Conversion of Actual System Network to a Single Equivalent Impedance

The theory of converting a complex network to an equivalent single impedance is not new. The principle is stated in Thévenin's theorem which is found in many electrical engineering textbooks.

In diagrammatical form, the principle is illustrated in Fig. 1. It is seen that a system network composed of generators, circuits, and loads may all be reduced, with respect to load X, to the equivalent system shown in the lower portion of Fig. 1. The generator or input voltage to the equivalent circuit is equal to the open circuit voltage (hereafter designated as E_{OC}) measured at the load X terminal. The equivalent impedance Z_D is that impedance as seen looking into the network at load X (sometimes referred to as the driving-point impedance at load X). E_{OC} and Z_D can be manually calculated for simple radial systems or must be measured with the aid of a network analyzer for complex network systems of the type shown in Fig. 1.

When use is made of the network analyzer, E_{OC} is measured by removing the load at the point of interest while maintaining constant generator bus voltage. Z_D may be determined in two ways. The first method consists of removing the load at the point of interest, grounding all generator buses, and applying a known voltage E_D at the point of interest on the network. The phasor ratio of the voltage E_D to the current flow into the network is the driving-point impedance Z_D and is obtained in complex form on the analyzer. The second method of obtaining Z_D consists of short-circuiting the load bus while maintaining constant generator bus voltages and measuring the short-circuit current I_{SC} in complex form with the previously measured voltage E_{OC} as reference. The phasor ratio of E_{OC}/I_{SC} is the complex impedance Z_D. These measurements are illustrated in Fig. 2.

Measurements of E_{OC} and Z_D may be required for peak load conditions and for light load conditions. Ordinarily the peak load measurements will suffice. An example is given showing the manual calculation of E_{OC} and Z_D in Appendix I for a single transmission line with line-charging capacitance included. An additional example is given in reference 1.

Step 2—Conversion of the Single Equivalent Impedance to 1.0 PU

The previous discussion showed how a complex network system can be converted to a single impedance Z_D whose input voltage is E_{OC}. For convenience of computation, it is desirable to convert E_{OC} and Z_D to 1.0 pu. If all equivalent impedances as viewed from any load point on a network are converted to 1.0 pu with a 1.0 pu input voltage, the voltage regulation characteristics of the network, viewed from the various load points, can be easily obtained from a single set of unit impedance power-reactive circle diagrams. The advantage is that one set of circle diagrams may be used for all problems of a similar nature, removing the necessity of redrawing a new set for each new problem.

The unit impedance concept was originated by Miller and Robbins.[1] In their work, it was shown that a simple radial-type power system could be resolved into a single unit impedance of varying resistance-reactance (R/X) ratio and supplied by a single generator having a terminal voltage of 1.0 pu. Such a representation required that the base kva be determined from the value of the total impedance rather than being selected arbitrarily as is the usual case. These concepts are used here and extended to include the resolution of a complex network system into a unit impedance equivalent, as viewed from any single load point on the network. As previously indicated, this is done by letting E_{OC} and Z_D be the base kilovolts (kv) and ohms respectively.

Recalling a familiar expression, found in many reference sources,[2] impedance can be expressed in pu form on a 3-phase system as

$$Z \text{ in pu} = \frac{Z \text{ ohms} \times \text{base kva}}{1{,}000\ (\text{base kv})^2} \tag{1}$$

Since it is desired to make Z always equal to 1.0 pu, equation 1 is rearranged to solve for the base kva

$$\text{Base kva} = \frac{(\text{base kv})^2 1{,}000}{Z \text{ ohms}} \tag{2}$$

Substituting Z_D and making the base kv equal to E_{OC}

$$\text{Base kva} = \frac{(E_{OC})^2 1{,}000}{Z_D \text{ ohms}} \tag{3}$$

where E_{OC} is in line-to-line kv.

Hence, equation 3 determines the base kva when E_{CO} and Z_D are made the base kv and base ohms respectively. The base kva may also be determined using known values of E_{OC} and I_{SC} as obtained in Fig. 2.

$$\text{Base kva} = \sqrt{3} E_{OC} I_{SC} \tag{4}$$

where I_{SC} is the short-circuit current measured at the load point in question; see Fig. 2.

Frequently, E_{OC}, Z_D, and I_{SC} will be measured in per cent or pu on some arbitrary base kv and kva, particularly if the values are obtained from network analyzer measurements. Since it is desired that E_{OC} and Z_D be made the base kv and base ohms, the new base kva must be determined as follows

$$Z_D = 1.0 \text{ pu} = z_d \left(\frac{\text{new base kva}}{\text{old base kva}}\right) \times \left(\frac{\text{old base kv}}{E_{OC}}\right)^2 \tag{5}$$

where z_d is in pu on the old base kv and kva.

Rearranging and solving for the new base kva

$$\text{new base kva} = \frac{\text{old base kva}}{z_d(\text{pu})} \times \left(\frac{E_{OC}}{\text{old base kv}}\right)^2 \tag{6}$$

Either equations 3, 4, or 6 may be used to determine the proper base kva depending on whether values of E_{OC} and I_{SC} or E_{OC} and Z_D are given in pu form or in kv, amperes, or ohms.

Having determined the proper base kva, the power and reactive load flowing at the point in question on the network are expressed in pu on the calculated base kva as follows

$$\text{pu power load} = \frac{\text{actual kilowatts}}{\text{base kva}} \tag{7}$$

$$\text{pu reactive load} = \frac{\text{actual kilovars}}{\text{base kva}} \tag{8}$$

To illustrate the use of the foregoing relations, Fig. 3 shows the load-flow diagram of an actual 115-kv transmission network which was studied on an a-c network analyzer. It was desired that the voltage regulation characteristics of the network at the substation bus R' be determined using the principles described herein. Measurements of E_{OC}, I_{SC}, and Z_D were taken at bus R'. They are

$E_{OC} = 1.078\,\underline{/0^\circ}$ pu
$I_{SC} = 1.68\,\underline{/-86.16^\circ}$ pu
$Z_D = 0.043 + j.640$ pu

The base kv and kva of the network are 115 kv and 100,000 kva respectively.

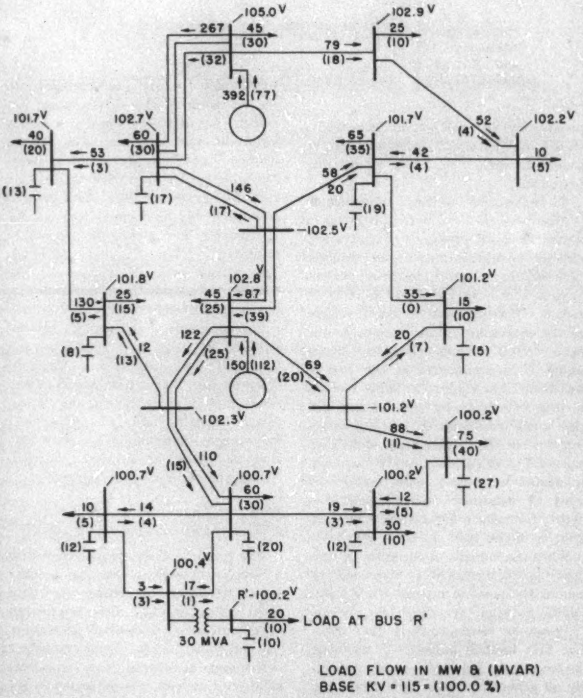

Fig. 3. Typical load-flow diagram, 115-kv system

Fig. 4 (left). Unit impedance-unit input voltage equivalent circuit

E_{OC} = 1.0 PER UNIT

Z_D = 1.0 PER UNIT AT VARIABLE X/R RATIO

E_2 IS IN PER UNIT OF E_{OC}

BASE KVA = $\dfrac{(E_{OC})^2 \cdot 1000}{Z_D \text{ OHMS}}$; WHERE E_{OC} IN THIS EXPRESSION IS IN ACTUAL LINE-TO-LINE KILOVOLTS.

$P_2 = \dfrac{\text{ACTUAL KW}}{\text{BASE KVA}}$ IN PER UNIT

$Q_2 = \dfrac{\text{ACTUAL KVAR}}{\text{BASE KVA}}$ IN PER UNIT

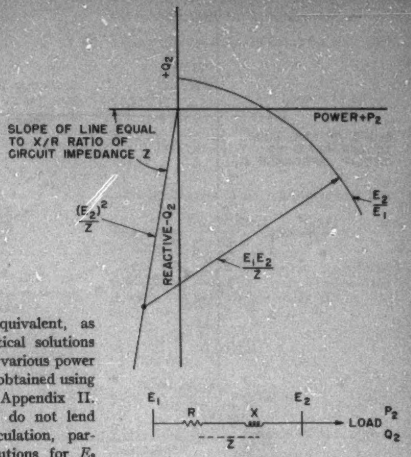

Fig. 5 (right). General construction of power-reactive circle diagram

These measured quantities were made using the methods which are illustrated in Fig. 2.

As a check on the measured value for Z_D

$$Z_D=\frac{E_{OC}}{I_{SC}}=\frac{1.078\,\underline{/0^\circ}}{1.68\,\underline{/-86.16^\circ}}$$

$$=0.043+j.640=0.641 \text{ at } X/R=14.9$$

Letting E_{OC} and Z_D be equal to 1.0 pu, and solving for the new base kva using equation 6

$$\text{New base kva}=\frac{100{,}000}{0.641}\left(\frac{1.078\times 115}{115}\right)^2$$
$$=181{,}000 \text{ kva}$$

as a check, the new base kva may also be calculated as follows, using equation 4 slightly modified

$$\text{New base kva}=E_{OC}I_{SC} \text{ base kva}$$

where E_{OC} and I_{SC} are in pu on the original network base kva and kv.

$$\text{New base kva}=1.078\times 1.68\times 100{,}000$$
$$=181{,}000 \text{ kva}$$

If a load of 10,000 kw and 5,000 kilovars were flowing to the load at bus R', these values can be expressed in pu on the new kva base using equations 7 and 8

$$\text{pu power load}=\frac{10{,}000}{181{,}000}=0.0552$$

$$\text{pu reactive load}=\frac{5{,}000}{181{,}000}=0.0276$$

Appendix I gives an example of transforming a single transmission line into a unit impedance-unit input voltage equivalent circuit using the pu system. Fig. 4 shows the final resulting pu equivalent circuit to which all original circuit configurations are transformed.

Step 3—Use of Unit Impedance Power-Reactive Circle Diagrams

The equivalent impedance of a network, as viewed from any load point on the network, can be converted to a single unit impedance equivalent, as shown in Fig. 4. Analytical solutions for the load voltage E_2 for various power and reactive loads may be obtained using the equations given in Appendix II. However, these equations do not lend themselves to rapid calculation, particularly when many solutions for E_2 are desired as a result of varying the power and reactive load. Power-reactive circle diagram solutions for E_2 can be quickly obtained particularly when the diagrams do not have to be replotted for each new problem which might arise.

The general method of constructing a power-reactive circle diagram is indicated in Fig. 5. A complete discussion of this subject is given in reference 3. It will be noted, in Fig. 5, that three quantities must be obtained in the construction of a single circle. These are:

E_2^2/Z = distance to the center of the circle from the zero co-ordinates

E_1E_2/Z = radius of the circle

X/R = slope of the line upon which the center of the circle is located

Since $E_1=E_{OC}=1.0$ pu and $Z=Z_D=1.0$ pu, the three quantities reduce to E_2^2, E_2, and the X/R ratio respectively. This is illustrated in Fig. 6.

Several circles can be plotted for different values of E_2 on the same graph, as indicated in Fig. 7. It is seen that the X/R ratio of the impedance Z_D can assume different values ranging from 20 to 1 depending on the point of measurement in a network. The circles need only be rotated in accordance with the X/R ratio of Z_D; see Fig. 8.

To eliminate the need of reproducing the circle diagrams for each new X/R ratio of Z_D, it is desirable to have a number of precalculated circles printed on transparent paper or a template. Such a template can then be rotated over standard rectangular co-ordinate graph paper so as to line up with any X/R ratio that might be encountered.

An Illustrative Example in the Use of Unit Impedance Power-Reactive Diagrams

It was shown previously that the 115-kv system network, shown in Fig. 3, could be reduced to a single equivalent unit impedance, as shown in Fig. 4. The measured and derived quantities pertaining to the equivalent circuit of the network were: $E_{OC}=1.0$ pu or $1.078\times 115=124$ kv; $Z_D=1.0$ pu; X/R ratio = 14.9; and base kva = 181,000.

Using these quantities, power-reactive circle diagrams were constructed and are shown in the lower portion of Fig. 9 for receiving voltages E_2 of 0.95, 0.90, 0.85, and 0.80 pu of E_{OC}. These pu values of receiving voltage would correspond to 118, 111.8, 105.4, and 99.2 kv respectively. The voltage regulation characteristics of the network can be plotted as a function of load at bus R', Fig. 3, where, for illustrative purposes, it has a kilovar/kilowatt ratio of 0.5 which is nearly a 90-per-cent power-factor load. A constant load line of kilovar/kilowatt = 0.5 is plotted, as shown in Fig. 9. Where the load line intersects the constant voltage circles, indicate the pu value of power required to produce the indicated values of receiving voltage E_2. The upper portion of Fig. 9 shows the voltage regulation curve of E_2 plotted as a function of pu power. The voltage regulation curve of Fig. 9, permits the determination of the receiving voltage E_2 for any specific value of power having a ratio of kilovar/kilowatt equal to 0.5. Table I. Comparison of E_2 and Measured Values

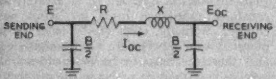
Load		E_2 (Obtained from Analyzer), Kv	E_2 (Obtained from Fig. 9), Kv
Megawatt	Megavars		
0	0	124	124
10	5	120	120
20	10	115.2	115
30	15	100.2	108.8
40	20	101.0	100.8

E_2 obtained from Fig. 9 and the actual measured values obtained from the network analyzer for several values of power. As seen, the agreement is very good. Greater accuracy can be obtained if the scale used in plotting the power-reactive diagrams is increased.

Unit impedance power-reactive circle diagrams are not restricted to the analysis of voltage regulation problems alone. They may also be used to calculate power and reactive loss on transmission lines and radial-type multiple circuit systems. In addition, they are very educational as a means of showing the effect of changing circuit X/R ratio on voltage drop or the reactive requirements at the load for maintaining a constant per-cent voltage drop.

Appendix I. Conversion of a Transmission Line to a Unit Impedance Circuit

A single 3-phase transmission line can be converted to a unit impedance circuit following steps 1 and 2 described in the paper. The transmission-line configuration is assumed as a π circuit



where

R = total resistance, ohms per phase
X = total reactance, ohms per phase
B = total line-charging susceptance, mhos per phase

Determine the open circuit voltage E_{OC} at the receiving end when a 3-phase voltage E is applied to the sending end terminal

$$I_{OC}=E_{OC}\frac{B}{2} \tag{9}$$

also

$$I_{OC}=\frac{E}{R+J\left(X-\frac{2}{B}\right)} \tag{10}$$

Substituting equation 10 into equation 9 and solving for E_{OC} magnitude

$$E_{OC}=\frac{2}{B}\frac{E}{\sqrt{R^2+\left(X-\frac{2}{B}\right)^2}} \tag{11}$$

Determine the driving-point impedance Z_D of the transmission line as viewed from the receiving terminal. This is done by grounding the sending-end terminal and measuring the impedance Z_D looking into the receiving terminal

$$Z_D=\frac{(R+JX)\left(-J\frac{2}{B}\right)}{(R+JX)+\left(-J\frac{2}{B}\right)} \tag{12}$$

The original transmission circuit can now be replaced by the following equivalent circuit using Thévenin's theorem

where

$$Z_D=\frac{(R+JX)\left(-J\frac{2}{B}\right)}{(R+JX)+\left(-J\frac{2}{B}\right)}$$

and

$$E_{OC}=\frac{2}{B}\frac{E}{\sqrt{R^2+\left(X-\frac{2}{B}\right)^2}}$$

The equivalent circuit can be converted to the following pu form using the methods described in step 2 of the paper

where

$$E_{OC}=\frac{2E}{B\sqrt{R^2+\left(X-\frac{2}{B}\right)^2}}=\text{base kv}$$

E = the actual sending-end voltage, 3-phase line-to-line kv

$$Z_D=\frac{(R+JX)\left(-J\frac{2}{B}\right)}{(R+JX)+\left(-J\frac{2}{B}\right)}=\text{base ohms}$$

$$\text{base kva}=\frac{(E_{OC})^2}{Z_D}\,1{,}000 \tag{13}$$
